THE CHEMISTRY OF THE TERPENES. By F. Heusler, Ph.D., Privatdocent of Chemistry in the University of Bonn. Authorized Translation by Francis J. Pond, M.A., Ph.D., Assistant Professor in the Pennsylvania State College. Carefully Revised, Enlarged and Corrected. Cloth. Pp. 457. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co. 1902.

The production of a good English translation of Heusler's book on the terpenes will be welcomed by many English-speaking chemists, and the fact that in the translation the rapidly expanding subject matter has been brought up to date will, of course, make this edition more valuable than the original. Heusler's work was originally published as a part of a "Handworterbuch" of chemistry, with the purpose of collecting the scattered material of this important and interesting branch of organic chemistry. It consists, therefore, of an introductory chapter with general considerations, followed by a classification and description of the members of both the terpenes and the closely related compounds. While probably as much space as is warranted is given to the matter of properties and preparation of the innumerable derivatives, the worker will undoubtedly find its greatest use as a classified and intelligent directory to the original papers from which it is compiled, and abundant provision for this is made in the references as quoted. The translator has made most acceptable English of the original, in addition to adding the newer material without wedging it conspicuously into the text.

Medical Organization.

As Oregon Understands It.

We quote as follows from the October number of the *Medical Sentinel:*

OUR NEW CONSTITUTION.

"If progress consists, as we have been led to believe, in adjustment to a continually changing environment, the Oregon State Medical Association took a long step in advance at its recent meeting. First, in the adoption of the model constitution suggested by a committee of the A. M. A. for state organizations, thus placing itself in affiliation with the majority of all the states in the Union and in step with the great, national march of medical progress. It is true that in doing so it incidentally legislated out of existence its own former membership and self, but this defect will be readily remedied before the next meeting, and we shall have the great advantage of a clean start all round on a broader basis. A committee has been left in charge of the accouchement and will no doubt deliver safely. The change is one which makes for breadth of view and harmony of effort in every direction. It adequately recognizes for the first time in the history of the Association the essential solidarity of the medical profession in spite of the sects and cliques into which it may have allowed itself to become divided.

ALL THE WORLD IS OUR PARISH.

"The note of a broad, manly and tolerant catholicity is most clearly struck in the language of the section on membership, of the newly-adopted constitution:

It shall promote friendly intercourse between physicians of the same locality, and shall continue these efforts *until every physician, in every county in the state, who can be made reputable has been brought under medical society influence.*

"This means, of course, the ignoring of the individual likes and dislikes, to which the medical profession is so peculiarly and painfully prone, the recognition that all who are laboring for the health, the sanitary education and the welfare of the community, have a common ground upon which they can unite, in spite of personal differences of opinion or even of ethics. Just as there are exceedingly few men in whom the good does not far outweigh the bad, there are very few, indeed, of our professional brethren with whom our points of agreement are not at least three times as numerous and important as our points of disagreement. Nor need we fear that by such broadening of our platform have we in any way weakened our principles or lowered our standards. On the contrary, we believe that they will be strengthened thereby. Any really representative gathering of men practicing according to the Code of Ethics of the American Medical Association which, after all, is simply the code of the honest man and the gentleman, any gathering, to become a member of which 'full and ample notice and opportunity has been given to every such physician in the county,' need ever be a subject of doubt as to its overwhelming majority in favor of the right, the honorable and the courteous thing in any emergency that may arise. The competent, scientific and honorable element will surely dominate and benefit the less desirable members, if any such there be, while the mischief makers will find themselves with far less power for harm inside such an organization than they had outside of it. As Marcus Aurelius long ago pointed out, 'No man can injure us save by our own consent,' and the man who was injured most by the petty dislikes and jealousies, nay even the righteous indignation and disapproval, which have made the 'differences' of doctors a by-word and a reproach in the mouths of the laity from time immemorial, was not the object of these feelings but the man who harbored them.

PERSONAL PREFERENCES BARRED.

"As a necessary corollary it seems to us, of this more strictly professional, scientific and humanitarian basis of unity, came the second marked change in the organic law of the Association, that of ruling out the principle of the black-ball. From par-

ticipation in the great work of professional and humanitarian progress no man must be debarred except for cause and by the judgment of his peers. The secret black-ball, with its utter absence of responsibility, the impossibility of ascertaining its source, while eminently proper in and well adapted to the needs of a social club, where the first requisite of all is good fellowship, 'clubability,' and the exclusion of any individual who would become a jarring note in the harmony, is entirely out of place in broad, representative, public organizations. Any man who is considered by the majority of his peers to be fit and worthy to lend a hand in the great work, is certainly entitled to that privilege, even though there be, in the body with which he wishes to unite, a dozen men who happen to dislike him on personal grounds, however valid these grounds may seem to the individuals holding them. A man who will allow purely personal considerations to interfere in this way with his business relationships, his political affinities, his religious or philanthropic affiliations would speedily find himself either in an exclusive organization of one, or making a successful failure at ever point. Yet this is, in our judgment, what the medical profession has done far too extensively in the past; and is one of the secrets of the small amount of consideration which it can demand as a right in either politics, business or philanthropic affairs. But it is not, thank Heaven, a necessary part of our mental make-up, as our enemies have cheerfully assumed, and we propose to be rid of it in the future.

THE FREEDOM OF SCIENCE.

"The second necessary corollary of this broad and impersonal position is embodied in the clause of our new constitution making eligible to membership every reputable and legally qualified physician, practicing according to the Code of Ethics of the American Medical Association, *who will agree not to practice sectarian medicine.* This, which is likely to be bitterly bemoaned as another lowering of our professional standards, is really nothing more than the incorporation into our Constitution of what has long been our unwritten law and avowed belief. We have all along contended that there was no need for any school of medicine terming itself 'eclectic,' as we, the regulars, were eclectic in every true sense of the term, choosing from whatever source, everything which had been proved to be good. Our issue with the homeopathic division lay, not in the fact that we did not believe in the principle of 'similia,' as such, for we have never been 'allopaths' except in the mouths of our enemies. On the contrary, we just as promptly and emphatically disavow the principle of '*dissimilia*,' for what we object to is merely the holding of any single, exclusive and universally applicable principle in the treatment of all diseases. We would rule out any man who called himself an 'allopath' just as promptly as one who called himself a homeopath. Our practice is based solely on the discoveries of science, checked by the experience of the past, and any man of average intelligence and sufficient training to pass a state board of examiners is at liberty and welcome to use any remedies or methods of treatment, which commend themselves to his judgment. If his views are mistaken he will be the severest sufferer by them and we can leave the question of who is right, as the spirit of true agnosticism has taught us must everywhere be done, to the slow but sure arbitrament of time. And it will do us no harm to remember, as an excellent antidote for any Pharisaical tendencies, that the exclusive principle of *similia* is no new and peculiar thing or method, but a survival of the equally irrational and exclusive principles of treatment firmly believed in by our own direct ancestors of no very recent date. The briefest study of the doctrine of signatures, the principle of contraries, the Brunonian system and the antiphlogistic methods of treatment, which persisted to within even the memory of most of us, ought to diffuse an atmosphere of sympathy around our feelings toward our single-principle brethren."

St. Francis County (Ark.) Medical Society.

On Dec. 5, 1902, the physicians of St. Francis County, Ark., organized a medical society at Forrest City, known as the St. Francis County Medical Society, with Dr. James D. McKnight as president, and Dr. James O. Rush, secretary, both of Forrest City.

Warren County (Ohio) Medical Society.

At the regular meeting of this society the committee on constitution reported favorably on the reorganization movement but asked to be retained till the next regular meeting, when they will make a fuller report. The society gave a banquet in honor of Drs. John M. Withrow and Brooks F. Beebe, Cincinnati, and Dr. Horace Bonner, Dayton.

Delta County (Mich.) Medical Society.

This society was reorganized Nov. 25, 1903, along the lines adopted by the American Medical Association. Drs. Theodore A. Felch, Ishpeming, councilor for the Twelfth District; Beverly D. Hanson, Sault Ste. Marie, secretary of the State Board of Registration,, and Norman Kerr, Chicago, spoke in favor of the plan. The following officers were elected: Dr. David N. Kee, Gladstone, president; Dr. Albert L. Laing, Rapid River, vice-president; Dr. Harry W. Long, Escanaba, secretary, and Dr. William Elliott, Escanaba, treasurer.

Omaha-Douglas County (Neb.) Medical Society.

This society, in annual session, elected as officers for 1903 the following: President, Dr. William H. Christie; vice-presidents, Drs. H. P. Hamilton and F. W. Faulk; secretary, Dr. J. M. Aikin; treasurer, Dr. Millard Langfeld, and board of censors, Drs. Benjamin F. Crummer, Andrew B. Somers, and Samuel K. Spalding. The society is reorganized on the American Medical Association plan. Sixteen new applications were filed with the secretary. A banquet followed at which Drs. Harry M. McClanahan and Byron B. Davis made clear to all present the plan and advantages of reorganization.

Societies.

Hickman County (Tenn.) Medical Society.—At the annual meeting, held Dec. 1, 1902, Dr. Charles V. Stephenson, Ætna, was elected president; Dr. Andrew Norris, Centreville, vice-president, and Dr. W. I. Pace, Tom's Creek, secretary.

Indianapolis (Ind.) Medical Society.—At the annual meeting of this society, January 6, Dr. William E. Jeffries was elected president; Dr. John F. Barnhill, vice-president; Dr. Theodore Potter, secretary, and Dr. John T. Scott, treasurer.

German Medical Society (Cleveland).—At the annual meeting of this society, January 8, Dr. Samuel Riegelhaupt was elected president; Dr. Walter G. Stern, vice-president; Dr. Morits Lowenthal, secretary, and Dr. Isador J. Propper, treasurer.

Johnson County (Iowa) Medical Society.—At its annual meeting in Iowa City, January 6, Dr. Elmer F. Clapp was elected president; Dr. Lola D. Clark-Mighell, vice-president, and Dr. Joseph A. Valenta, secretary and treasurer, all of Iowa City.

Dayton (Ohio) Academy of Medicine.—Dr. Thomas E. Marshall was elected president; Dr. William A. Ewing, vice-president; Dr. Fred C. Weaver, secretary, and Dr. William A. Burns, treasurer of the academy, at its annual meeting January 9.

Garrard County (Ky.) Medical Society.—At the annual meeting of this society at Lancaster, Dr. William G. Casenburg, Point Lick, was elected president; Dr. William Burnette, Lancaster, vice-president, and Dr. Hugh M. Grant, Lancaster, secretary and treasurer.

Los Angeles (East Side) Medical Association.—This association, at its annual meeting, Dec. 29, 1902, elected Dr. John M. Armstrong, president; Dr. Martha P. T. Wagstaff, vice-president; Dr. Robert C. Dundas, secretary, and Dr. Harry B. Fasig, treasurer.

Philadelphia Obstetrical Society.—At the annual election of this society, January 2, the following officers were elected: President, Dr. John M. Fisher; vice-presidents, Drs. Richard C. Norris and Wilmer Krusen; secretary, Dr. Frank C. Hammond, and treasurer, Dr. John W. West.

City Hospital (St. Louis) Alumni Association.—At the annual meeting and dinner of this association, held January 8, Dr. Horace W. Soper was elected president; Dr. J. C. Folk, vice-president; Dr. Rutherford B. H. Gradwohl, secretary, and Dr. Hudson Talbott, treasurer, all of St. Louis.

Clinton County (Iowa) Medical Society.—This society held its annual meeting at Clinton, January 6, and elected Dr.

Frank A. Hohenschuh, president: Peter S. Kaadt, vice-president: Dr. Harry R. Reynolds, secretary and treasurer, and Christian Jousson, librarian, all of Clinton.

Jackson County (Mich.) Medical Society.—This society, at its second annual meeting, held in Jackson, elected officers as follows: President, Dr. Nathan H. Williams; vice-president, Dr. Delbert E. Robinson; secretary, Dr. R. Grace Hendricks, and treasurer, Dr. Frederick W. Rogers, all of Jackson.

Howard County (Mo.) Medical Society.—At the annual meeting of this society, held at Fayette, Dr. Charles H. Lee, Fayette, was elected president; Dr. Vaughan Q. Bonham, New Franklin, first vice-president; Dr. Joel Y. Hume, Armstrong, second vice-president, and Dr. C. W. Watts, Fayette, secretary and treasurer.

Hartford (Conn.) Medical Society.—At the annual meeting of this society, held January 5, Dr. William T. Bacon was elected president; Dr. John O'Flaherty, vice-president; Dr. William G. Craig, secretary; Dr. Arthur D. Hayes, assistant secretary; Dr. George K. Welch, treasurer, and Dr. Walter R. Steiner, librarian.

Ingham County (Mich.) Medical Society.—At the annual meeting of this society in Lansing, January 8, the officers elected at the meeting for organization, Nov. 13, 1902, were re-elected as follows: Dr. Sydney H. Culver, Mason, president; Dr. Harry H. Haze, Lansing, vice-president, and Dr. L. Anna Ballard, Lansing, secretary and treasurer.

Missouri State Medical Association.—The date of the annual meeting of this society at Excelsior Springs has been changed from May 19 to 21 to April 21 to 23. Drs. E. Lowrey, J. J. Gaines, W. S. Wallace and A. C. O'Kell, Excelsior Springs, announce that they will be glad to make arrangements for board and accommodation for visiting members who will apply to them.

Medical Society of the District of Columbia.—At the stated meeting of this society, held January 5, the following officers were elected: Dr. George M. Kober, president; Drs. D. Kerfoot Shute, and Dr. Benjamin G. Pool, vice-presidents; Dr. Charles W. Franzoni, treasurer; Dr. Francis P. Morgan, recording secretary, and Dr. Thomas C. Smith, corresponding secretary.

Gulf Coast (Miss.) Medical Society.—The annual meeting of this society was held at Scranton, Miss., January 7. A new constitution and by-laws were adopted and Dr. Benjamin F. Duke, Pascagoula, was elected president; Dr. M. Lyle Talbot, Biloxi, vice-president; Dr. Jacob N. Rape, Moss Point, secretary and treasurer, and Dr. Joseph A. Tabor, Scranton, corresponding secretary.

Freeborn County (Minn.) Medical Society.—At a meeting of the physicians of the county, at Albert Lea, January 9, a county society was organized, with the following officers: President, Dr. Albert C. Wedge, Albert Lea; vice-president, Dr. William L. Palmer, Glenville; secretary, Dr. Hamilton H. Wilcox, Albert Lea, and treasurer, Dr. John P. Von Berg. The society also adopted a fee-bill.

Alpha Kappa Kappa Fraternity.—The eighth annual convention of this body was held in Chicago, January 2. Dr. George Cook, Concord, N. H., was elected president; Dr. John I. French, Boston, vice-president; Dr. Edward L. Heintz, Chicago, secretary, and Dr. E. R. Pfarre, New York, treasurer. At the annual banquet tendered by the three local chapters, Dr. Archibald Church presided as toastmaster.

Somerville (Mass.) Medical Society.—The annual meeting of this society took place at the Somerville Hospital January 6. The following officers were elected: President, Dr. Frederick G. Smith; vice-president, Dr. Douglas S. Flewelling, and secretary and treasurer, Dr. Charles E. Mongan. Resolutions of sympathy were passed on the death of Dr. John F. Couch, a former president of this society.

Kansas State Medical Association, Third District Auxiliary.—The organization of a district auxiliary to the state association was effected at Concordia, January 9. The following officers were elected: President, Dr. William F. Sawhill, Concordia; vice-president, Dr. Josephus P. Stewart, Clay Center; secretary, Dr. Michael R. Spessard, Glen Elder, and Treasurer, Dr. Frank M. Daily, Beloit.

Clark County (Ohio) Medical Society.—At the annual meeting of this society in Springfield, January 5, the following officers were elected: President, Dr. John E. Myers; vice-presidents, Drs. Clarence S. Ramsey and Theodore F. Bliss; secretary, Dr. Charles L. Minor; treasurer, Dr. Chester B. Bliss, and executive committee, Drs. Joseph A. Link, Clinton M. Hiestand and Charles W. Evans, all of Springfield. Dr. Bonner of Dayton, councilor for the district, addressed the society on the benefits to be derived from reorganization.

Orleans Parish (La.) Medical Society.—At the annual meeting of this society, January 10, in New Orleans, the following officers were installed: President, Dr. Edwin J. Graner; vice-presidents, Drs. Jacob A. Storck, Oliver L. Pothier and O. Joachim; secretary, Dr. Samuel D. Clark; treasurer, Dr. William H. Seemann; librarian, Dr. Homer Dupuy, and additional members of board of directors, Drs. Hermann B. Gessner, John Callan and Henry D. Bruns. Mr. Charles Rosen, the annual orator, spoke on "The Duty of Medical Men as Medicolegal Experts."

Johnson County (Mo.) Medical Society.—The physicians of Johnson County met at Warrensburg and effected an organization, Dec. 12, 1902. The following officers were elected: Dr. James I. Anderson, Warrensburg, president; Drs. Leander F. Murray, Holden, and Milton P. Shy, Knobnoster, vice-presidents; Dr. Edwin H. Gilbert, Warrensburg, secretary, and Dr. J. Alfred Adcock, Warrensburg, treasurer. Dr. M. P. Overholzer, Harrisonville, vice-president of the Medical Association of Missouri, addressed the society on "Organization of the Medical Profession."

EGYPTIAN MEDICAL CONGRESS.

First Congress, held in Cairo, Egypt, Dec. 18 to 24, 1902.
(From our Special Correspondent.)

The first Egyptian Medical Congress, in point of attendance, exceeded all expectations, more than 600 medical men taking part. Germany, Austria, Belgium, Switzerland, France, Italy, Russia, Persia, Great Britain, and the United States were represented. The congress was opened informally on the evening of December 18, by a reception given to the delegates at the Continental Hotel.

The Addresses of Welcome.

On the morning of December 19 the congress was formally opened by the Khedive, at the Khedival Opera House. He was accompanied by all his ministers. The stage was occupied by the delegates who represented countries. The Khedive made a short address, in which he welcomed the delegates to Egypt and expressed the opinion that no doubt much good would result from the scientific sessions. He was followed by S. E. Ibrahim Pacha Hassan, the president of the congress, who stated that they felt very much flattered that so many scientific men should come to their ancient country to discuss with them scientific subjects. They would do all in their power to show that their welcome was cordial and sincere. The following men replied in the order named: For Germany, Dr. Nolda; Austria, Professor Nothnagel; Belgium, Dr. Eid; United States, Major Gorgas, U. S. A.; France, Professor Bouchard; Great Britain, Dr. Reginald Harrison; Hungary, Prof. Karl Hoor; Italy, Professor Maragliano; Persia, Mirza Mohamed M. Khan; Russia, Prof. Pawloff; Switzerland, Professor Eternod. Professor Bouchard made the address on medicine, after which the meeting closed.

The Social Features.

In the afternoon the Khedive received the delegates at the Abdine Palace. He welcomed each one personally, and took occasion thereby to express his thanks to the country which he represented, for the kindness in sending him. On the evening of December 19 an Arab open-air fête was given at the pyramids. Special street cars were provided for the guests to make this journey of twelve miles. The fête consisted of exhibitions of Arab horsemanship, native dances, the illumination of the sphinx by various colored lights, etc. This was followed by a midnight lunch.

Arrangements of the Scientific Sessions.

On the morning of December 20 the scientific sessions were commenced. The work of the congress was divided into three sections, viz.: Internal Pathology, Surgery and Ophthalmology. The meetings were held at the Cairo School of Medicine. The buildings were admirably suited for the purpose. The Students' Club and the museums of the college were also placed at the service of the delegates. The sections met regularly from 9 to 12 a. m. and from 3 to 6 p. m. The hour from 12 to 1 was generally used for exhibiting clinical cases. Many cases of pellagra, leprosy, etc., were shown.

Cairo in many respects is an ideal place for holding a meeting to discuss tropical diseases. Many of the men were able to further demonstrate their papers by showing the cases clinically. Many of the diseases discussed are practically only found in Egypt as well as competent men to discuss them. There is also a certain amount of sentiment about Egypt as a meeting place. It was here that during the middle ages the spark of medicine was kept alive so that in later years it was available for kindling the brilliant light with which medicine shines to-day. We know that here over four thousand years ago the sulphur springs at Helwan, in the neighborhood of Cairo, were used for medicinal purposes.

On Sunday afternoon, December 21, the delegates were invited on board the Khedive's private yachts, which conveyed them to the barrage and his private gardens. The trip down the Nile was very much enjoyed. After the visitors had been given an opportunity to see the bridge and roam about the gardens, a lunch was served, after which the guests were taken back to Cairo by special trains.

On Monday evening, December 22, an Arab fête was given at the Maison Matatia. The invitations were extended by the president of the congress, S. E. Ibrahim Pacha, and Madame Pacha, and the secretary, Dr. Voronoff, and Madame Voronoff. The entertainment consisted of native chants and dances, snake charming, prestidigitateurs, etc. It was much enjoyed owing to its novelty. After the performance a sumptuous repast was provided.

The Delegates.

France had the largest delegation present, being represented by about 60 delegates. Italy came next in the point of numbers. Germany sent no official delegate; a number of Germans sojourning in Cairo temporarily represented her. Dr. Reginald Harrison, who represented the College of Physicians and Surgeons of Great Britain, has also another important mission here. He is investigating the extent of the course in medicine given at the Cairo School of Medicine, for the purpose of ascertaining how much value can be attached in England to a diploma granted here. The United States was represented by Major Gorgas of the United States Army, Assistant Surgeon Victor G. Heiser of the Public Health and Marine-Hospital Service, and Dr. C. G. Campbell, who represented the state of New York.

On the afternoon of December 23 the Minister of Public Instruction invited the delegates to visit the Museum of Antiquities. Every facility was given the visitors for making a thorough inspection. After the visit had been concluded, tea was served in a tent just outside of the museum.

On the afternoon of December 24 the Khedive gave a reception at the Abdine Palace in honor of the visiting delegates and their wives. After he had personally welcomed each one of his guests, a lunch was served. The unusual privilege of inspecting the palace was also accorded the visitors. This reception concluded the social functions.

The opinion was unanimously expressed on all sides that the entertainments provided were far greater in number and elaborateness than is generally the case at medical gatherings. When it is considered that this is an Oriental country and that matters which would be simplicity in themselves in other countries become here almost insurmountable barriers, it will be impossible to speak in too high words of praise of the committee and the medical men of Egypt who brought this about. The greatness of the task will also be better appreciated when it is remembered that the delegates came from many countries and spoke many languages. The success of the congress was due in a great measure to the indefatigable secretary, Dr. Voronoff, and his assistant, Dr. Bittar.

Summary of the Scientific Discussions.

The papers which excited the greatest amount of interest were those on tropical disease, the ones most discussed were bilharzia, pellagra, malaria, vesical calculi, dysentery and ankylostomiasis.

The disease most written about and discussed at the congress was undoubtedly bilharzia. As this disease occurs practically only in Egypt and its general characteristics are not generally known a brief outline of the disease is given below.

Much surprise was generally felt that the subject of cholera did not receive more attention. This was probably due to the fact that there seems to be a general unity of opinion among the medical men as to the methods to be employed in combating this disease.

Very little interest was shown on the subject of yellow fever, this being due, no doubt, to the fact that this disease rarely or never occurs here. The subject of dysentery received considerable attention and the statements of Dr. Kartoulis of Alexandria, a recognized authority on this disease, were considered very important.

Another important point brought out for the first time at this congress was the statement of Professor Loos that the ankylostoma penetrated the skin and gained entrance into the system in this manner. He demonstrated this by a number of tests. (See below.) The paper of Dr. Stiles of the Public Health and Marine-Hospital Service on the same subject was also considered an important contribution. He showed that the disease was much more common in the United States than was generally supposed, that it was pre-eminently a disease of sand areas and that Bentley's view, which is that ground itch is the initial symptom of the disease, is untenable.

Bilharzia.

Synopsis of the Disease.—Cause: *Bilharzia hæmatobia*, discovered by Professor Bilhartz. Lives in the portal vein, is unisexual, male measures from 5 to 12 millimeters in length. Fecundation takes place in the capillaries of the portal system. Ova are carried from there to all parts of the body, but seat of election is in the genito-urinary system. Found to be more common among the inhabitants of lower Egypt. Change of residence to another country usually has a tendency to make the symptoms in the milder form disappear, but they recur again on return to the country; 90 per cent. of cases are men, 10 per cent. women. The disease is introduced in the body in different ways. First, by the gastrointestinal route, the ova being present in drinking water or food. Second, by the organism penetrating the skin (?). (Latter route is supposed to be route of entrance in many cases, but it has not yet been satisfactorily demonstrated.—Loos and Wildt.) Causes abscesses of liver and particularly of the genito-urinary system, fistulas, tumors, etc. Principal constitutional symptom is the great anemia. Frequent cause of stone in the bladder in Egypt, the debris formed in the bladder acting as a nucleus and thus giving rise to stone formation. Eggs may generally be found in the few drops of blood that are passed at the end of micturition. Usually described as occurring in two forms, the mild and the grave. The mild form usually does not require surgical interference. Grave form is characterized by tumors, fistulas, abscesses, etc., which require surgical treatment. For further particulars as to surgical treatment see résumé of Dr. Wildt's paper given below. There is no specific medical treatment. General indications are for salol, santal, alkaline mineral waters and a tonic and symptomatic treatment.

Cholera.

The sum of the observations made on the recent epidemic of cholera indicates that water was the only means by which the disease was conveyed. It was found that wherever an infected locality was supplied with water that was free from cholera germs and the use of the ordinary water stopped, that the cholera disappeared or was greatly lessened almost at once. Wherever a person was found suffering with the cholera the patient was removed to an isolation hospital, and the floors of the house and the walls to a height of about five feet were washed with a lime solution. All fabrics were disinfected with steam, and where that was not possible boiling was used. All containers of fluids were broken, and new ones supplied. The containers among the natives consist almost entirely of crockery of some sort. In the villages where a pure water supply was not otherwise obtainable artesian wells were sunk. Nothing beyond what has been the treatment for cholera in the past was employed.

Below is given a brief résumé of the representative papers delivered before the different sections:

Section of Internal Pathology.

President, S. E. Dr. Comanos Pacha.

Dysentery.—Dr. Kartoulis of Alexandria said tropical dysentery is the only form which gives rise to abscess formation in the liver. Only cases not properly treated ever reach the stage of hepatic abscess. He states positively that from an experience based on hundreds of cases that no case of tropical dysentery should ever reach the abscess stage, and whenever they do, it is the fault of the attending physician. He states that ipecac and other remedies administered internally have their value, but that irrigation of the large intestine is the most essential thing. He uses for this purpose a solution of tannin. He states that other reliable observers have found irrigations with quinin, chlorate hydrate or carbolic acid solutions of great value. He also administers internally sodium salicylate or salicylic acid. The diet must be milk as nearly as possible.

Typhoid.—"The Early Diagnosis of Typhoid Fever by Blood Cultures." Dr. J. Courmont of Lyons claimed that by his method of making cultures from a patient suffering with typhoid fever a positive diagnosis could be made much earlier than by any other method. He claims great superiority over the Widal method because it is available much earlier in the disease.

Ankylostoma Duodenalis.—The object of this paper, by Professor Loos of the Cairo School of Medicine, was to show that the organism of ankylostomiasis can enter the system through the skin. He showed that this was possible by a number of reports of work he had done: 1. A culture of the organism was mixed with charcoal and smeared on a dog. No scarification or friction was employed for this purpose. In a definite number of cases the dogs showed symptoms of the disease, and on postmortem the typical lesions were found and the organism was recovered. 2. A culture of the organism was placed on the back of his own hand and accidentally left there. He himself developed the disease. 3. He showed numerous microscopic preparations in which the parasite could be seen to have passed through the skin.

Uncinariasis (ankylostomiasis).—"A Report on the Disease in the United States," by Dr. Stiles of the Public Health and Marine-Hospital Service, was read by Assistant Surgeon Victor G. Heiser. The points of this paper have been stated in THE JOURNAL. See January 3, p. 48, also pp. 28 and 36.

Surgical Section.

President, Dr. H. Milton.

The subjects which received most attention were bilharzia and stone in the bladder. The consensus of opinion was that liver abscesses due to bilharzia could be treated by puncture but that hospital facilities must always be available for such cases in which accidents occur. For bilharzia in other structures the surgical indications are the same as for like lesions due to other causes.

Lithotomy.—"The Hypogastric Operation for Stone." Dr. H. Wild said that surgeons are generally agreed that the following rules should govern the operation for stone in the bladder:

1. In stricture of the urethra perineal section is indicated because stricture can be treated at same operation.

2. Hypogastric operation is indicated in hypertrophy of prostate because it is the best operation to deal with the hypertrophy.

3. Hypogastric operation in cases of bad cystitis.

4. Hypogastric operation for encysted calculi. Majority of cases of this kind are due to bilharzia.

In addition to the indications given above for the hypogastric operation the author commenced to operate on all cases without choice by this method. The first 100 gave a mortality of 2. One died in 7 days and the other case in 3 weeks owing to renal suppuration. Both cases were afflicted with bilharzia.

An objection to lithoplaxy is that the cystoscope can not be introduced after this operation has been performed owing to bilharzia.

The hypogastric operation should always be done in the Trendelenburg position and without distending the bladder or rectum. The linear incision was always used.

The following are the general indications for the treatment of calculi in Egypt:

1. For small stones use lithoplaxy.

2. Great majority of cases which are complicated by bilharzia should be done with the hypogastric operation.

3. Unless special dexterity is possessed by the operator for lithoplaxy all cases which are complicated with bilharzia should be done with the hypogastric operation. Also cases in which the stone is very large.

Resolutions Planning Future Conferences.

At a general meeting held at 6 p. m., December 23, at the Continental Hotel, the following resolutions were adopted:

1. That the next Congress shall be held in 1907.
2. That a conference similar to the conference held at Venice, should be held soon in order to revise the quarantine regulations.
3. That measures be adopted for a more active sanitary surveillance at the Suez Canal and the Red Sea.
4. That separate pavilions be provided at general hospitals for the treatment of typhoid fever.

Concluding Business.

At a meeting held at the Khedival Opera House on December 24, the president, Dr. Ibrahim Pacha Hassan, in a short address, thanked the members of the congress for their meritorious work. The great success of the congress would cause the Khedive to write the date in letters of gold in the annals of Egypt.

A delegate from each country represented at the congress replied, and in a few appropriate remarks thanked the Khedive and the Egyptians for their kindness and hospitality.

Professor Nothnagel then made a brilliant address on prophylaxis, in which he stated that the efforts for the future must be directed more to prevention than to cure.

A resolution expressing sorrow over the untimely death of Major Reed, U. S. A., was read. The text of the resolution is as follows:

The members of the first Medical Congress held in Egypt learn with the most profound regret of the premature death of Major Reed of the Medical Corps of the United States Army.

The brilliant and important part that he took in the discovery that the stegomyia mosquito was the only agent that transmitted the organism of yellow fever, succeeding thereby to put the ravages of this terrible disease under the control of hygiene, makes his death a cruel loss to humanity.

The congress consequently decides to thus express on this occasion its sympathy with the Medical Corps of the U. S. Army and the family of Major Reed.

The congress also decides to beg of the secretary that he send through the proper channels a copy of this resolution to the Surgeon-General of the U. S. Army and one copy to Mrs. Reed.

After the transaction of some routine business, S. E. Fakhry Pacha, minister of public instruction, in the name of the Khedive declared the congress officially ended.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting of the Section on Medicine, Dec. 16, 1902.

James K. Crook, M.D., in the Chair.

A Brief Review of Some of the Etiologic Factors of Intestinal Dyspepsia.

DR. E. FRANKLIN SMITH adopted the classification of Dr. Hemmeter, viz.: 1. Intestinal dyspepsia due to abnormalities of secretion; 2, due to abnormalities of absorption, and 3, abnormalities of peristalsis. Heredity was supposed to play a very important part, while occupations involving grave responsibilities or severe nervous strain, predispose to this disorder. But little was known regarding the intestinal juice, and opinions varied greatly concerning the exact action of the bile; however, when the latter was reduced below the normal quantity, stagnation of the bowel contents occurred, with consequent fermentation, irritation and intestinal dyspepsia. The quantity of pancreatic secretion might be diminished by nervous influence, as well as by anemia, febrile disturbances, malignant disease of the pancreas, and the chewing of tobacco. The ingestion of excessive quantities of food, or the use of a diet in which certain ingredients were in excess, might cause intestinal dyspepsia. The imprudent use of drugs, especially laxatives,

was also a cause, and another common etiologic factor was the introduction of toxins with the food. Intestinal dyspepsia also arose as a result of abnormal bacterial activity, the bacteria gaining an entrance through a lesion of the epithelium. Again, intestinal dyspepsia might result from the abnormal performance of the function of the stomach, as, for example, when the hyperacidity of the gastric juice neutralizes the alkaline secretions of the small intestine and stops digestion. It should not be forgotten that a most prolific source of intestinal dyspepsia was to be found in deficient mastication and insalivation of the food. According to Boardman Reed, more than one-half of the cases of so-called nervous dyspepsia are dependent on actual disease in the gastrointestinal tract. Among other causes of intestinal dyspepsia might be mentioned the presence of certain toxic substances in the blood, the activity of intestinal parasites and increased peristalsis. The last-named presented itself under several different forms, but all of them were really neuroses.

Intestinal Digestion and Its Relation to Arterial Sclerosis and Renal Disease.

DR. LEONARD WEBER detailed the histories of three cases of chronic gastrointestinal indigestion which he had carefully observed for twenty-five years or more, and which had finally terminated fatally from interstitial nephritis. It was admitted, he said, that the toxemia associated with acute cases of infantile diarrhea was capable of causing acute nephritis; hence, why should not a chronic toxemia be capable of producing arterio-capillary and renal changes resulting in interstitial nephritis? In 1898, the speaker said, he had published a paper in which he had sought to prove that interstitial inflammatory processes in the kidneys were brought about through the toxins of tissue metabolism acting on the parenchyma of the urinary organs, and in this connection reported cases of already established renal and arterial sclerosis which had been greatly benefited by the persistent use of small doses of the iodids—five grains, three times a day.

Intestinal antisepsis should also be promoted by the more or less frequent use of calomel and lavage of the colon, and by a proper regulation of the diet. He was convinced that through faulty metabolism toxalbumins were produced, and more or less directly led to such constitutional diseases as gout and diabetes. For the purposes of early diagnosis examinations of the blood should prove of more service than analyses of the urine.

Treatment of Intestinal Indigestion; Remarks on Diagnosis.

DR. JOHN C. HEMMETER said that in achylia gastrica severe diarrheas were encountered. To recognize this dyspepsia, a test meal and an examination of the stool were necessary. The feces showed unchanged residue of meat, connective tissue, vegetable foods and perhaps fat residue. He believed that the most efficient means of counteracting dystrypsia due to pancreatic insufficiency was to bring about an appetite, as this was the normal stimulus to normal gastric digestion, and in turn to healthy pancreatic secretion. Experiments had proved the astounding fact that for every kind of food a gastric secretion was formed of definite and specific composition. Under the influence of appetite the gastric secretion furnished was more effective than that secreted under the purely chemical stimulus of food. Then again, there was reason to believe that the various kinds of food mutually advance or interfere with the digestion of their various constituents in the gastric chyme; hence, dietetic measures rather than drugs were indicated in the treatment. An unhygienic mixture of food containing an excess of carbohydrates, the various bacteria and fungi would cause excessive acid fermentation and would specially interfere with pancreatic digestion.

To distinguish between a catarrhal and a jejunal stool, it should be remembered that in the former there were present epithelia and round cells derived from the mucous membrane, while these were absent in the jejunal stool. The latter was rich in bile, had a slight fecal odor and a generally acid reaction. If dystrypsia were due to excessive carbohydrate or proteid ingestion, an exclusion of this particular class of food would be necessary. The seat of starch dystrypsia was in the small intestine. Remnants of meat fibers were always significant of abnormal intestinal indigestion, and if the nuclei in the muscle fiber were very evident, it pointed to an abnormality of the pancreatic secretion. The presence of an excessive amount of undigested connective tissue fibers when scraped raw beef had been taken, justified the conclusion that the gastric digestion was impaired. The appearance in the stools of drops of fat, or of fat crystals, was pathologic, but the presence of fatty soaps was of no diagnostic significance. With regard to treatment, the speaker said that so far the idea of the antitoxin treatment of the auto-intoxications was nothing more than a hopeful suggestion; the true treatment at present must be largely prophylactic and dietetic.

DR. W. W. VAN VALZAH said that for practical purposes he had found it sufficient to classify indigestion according as it was produced by an excess of animal food, of starchy foods and sugars, of the fat foods or of accessory foods, such as tea, coffee and condiments. That form due to animal food was characterized by an excessive production of indican and by foul stools with muscle fiber or connective tissue cells in them. The treatment consisted in restricting the use of such food for the time, the employment of lavage of the stomach and bowel, and the administration of 1/40 to 1/10 of a grain of calomel several times a day. If the indigestion were due to starchy foods or sugars, there would be an accumulation of gas in the large and small intestines, associated with either looseness or constipation, and perhaps with headache. Diminishing the quantity of such food and the administration of ichthyol or of salol, sodium bicarbonate or calcined magnesia constituted the treatment. Intestinal indigestion due to fat foods was shown by the presence of an excessive quantity of gas, by pain or burning, or the sense of uneasiness in the bowels. In many cases there was also a congestion of the liver.

Fatty foods must be reduced or stopped for a time, the stomach washed out and the engorged liver relieved by very small doses of mercurials, alkalies and mild laxatives, along with a very free use internally of pure water. Sufficient water should be used to keep the specific gravity of the urine down to the normal. If diarrhea were present, it could be controlled by the administration of chalk, tannin or similar preparations. All forms of intestinal indigestion called for careful regulation, not only of the diet, but of the sleep and exercise, and the promotion of a healthy mental state.

DR. MORRIS MANGES agreed with Dr. Hemmeter regarding the limited value of the ferments. Dr. Weber's paper, perhaps, explained the early occurrence of arteriosclerosis in some young subjects.

Therapeutics.

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns without allusion to inquirer.]

Calcium Chlorid.

Dr. Bertignon, in *Med. Press*, states that, after giving calcium chlorid a thorough trial, he has proved it to possess marked hemostatic properties. He claims to have succeeded in checking hemorrhages where ferric chlorid, antipyrin, ergotin and hot injections have failed. It may be employed in hemorrhages of whatever sort and in maladies presenting hemorrhagic complications such as hematemesis, hematuria, enterorrhagia, metrorrhagia, etc. It is recommended in intestinal hemorrhage complicating typhoid fever, administering a dram per rectum and half a dram by the mouth with a small dose of opium. It is also indicated in hemophylia given as follows:

℞.	Calcii chloridi	ʒi	4
	Syrupi opii	ʒiii	12
	Aquæ	ʒiv	120

Sig.: To be taken in divided doses in twenty-four hours and renewed as long as the hemorrhage lasts.

Frost Bites and Chilblains.

The following combinations are recommended by the *West. Druggist* in the treatment of frost bites and chilblains:

FROST BITES.

℞.	Tr. iodi	℥i	4
	Spts. etheris	℥x	40
	Collodii	℥iv	120

Misce. Sig.: Apply locally with a camel's hair brush; or:

℞.	Acidi tannici	gr. xxx	2
	Glycerini	℥ii	60

M. Sig.: Apply locally on gauze; or:

℞.	Balsami peru	℥iss	6
	Misturæ oleobalsam.	℥i	30
	Spts. cologne	℥i	30

M. Sig.: Apply locally by painting on the affected parts.

CHILBLAINS.

℞.	Creosoti		
	Liq. plumbi subacetatis, āā	gtt. xii	75
	Ext. opii	gr. iss	09
	Olei piceis liq.	℥iss	6
	Adipis	℥i	30

M. Ft. unguentum. Sig.: Apply locally; or:

℞.	Zinci oxidi	℥i	4
	Pulv. camphoræ		
	Pulv. myrrhæ		
	Pulv. opii, āā	gr. xxx	2
	Adipis	℥i	30

Misce. Allow the camphor to dissolve in the lard which has been melted by gentle heat, permit this to cool and mix with the other ingredients. Sig.: To be applied locally.

Diarrhea from Acute Intestinal Disorders.

The following is recommended by *Jour. of Tropical Med.* in the treatment of acute intestinal disorders, accompanied by pain and diarrhea:

℞.	Morphinæ mur.	gr. 1/12	005
	Ext. cannabis ind.	gr. 1/8	0075
	Nitroglycerini	gr. 1/600	0006
	Ext. hyoscyami	gr. 1/4	015
	Oleoresinæ capsici	gr. 1/20	003
	Ol. menth. pip	m. 1/20	003

M. Ft. capsulæ No. i. Sig.: One such capsule every three or four hours.

And in cases of dysentery the following:

R.	Acidi sulph. dil.	℥ss	15
	Tinct. opii deod.		
	Spts. camphoræ, āā	℥i	30
	Tinct. capsici		
	Spts. chloroformi, āā	℥ss	15
	Spts. vini gallici	℥iss	45

M. Sig.: One teaspoonful every two or three hours; or:

℞.	Magnesii sulph.	℥i	4
	Acidi sulph. dil.		
	Tinct. opii deod., āā	m. x	65
	Aq. chloroformi q. s. ad	℥ii	8

M. Sig.: To be taken at one dose and repeated in three hours. And in the diarrhea complicating typhoid fever the following is recommended:

℞.	Acidi carbol.		
	Ext. opii, āā	gr. i	06
	Bismuthi subnit.	gr. xviii	1 20

M. Ft. capsulæ No. vi. Sig.: One capsule three times a day.

Acute Catarrhal Bronchitis.

Danforth, in "Amer. Text-book of Applied Ther.," states, in those cases accompanied by marked pyrexia, dyspnea and hurried pulse, that the patient should be kept in bed and a vigorous cathartic given, such as Rochelle salts, ounce one half (15.), which may be repeated in four hours if necessary. If the pulse is full and strong the following mixture will be of service:

℞.	Tinct. aconiti rad.	℥ss	2
	Pot. bromidi	gr. lxxx	5
	Syr. zingiberis	℥iv	15
	Aquæ q. s. ad	℥ii	60

M. Sig.: One teaspoonful every two hours.

Large hot cataplasms of linseed meal, in which is thoroughly mixed a teaspoonful of mustard, should be applied locally. They should not be changed too frequently.

If the cough be dry and harassing the following combination is of value:

℞.	Codeinæ	gr. ii	12
	Pulv. ipecac.	gr. iii	18
	Pulv. camphoræ	gr. xxiv	50
	Quininæ sulph.	gr. xii	75

M. Ft. capsulæ No. xii.

As an expectorant mixture to render the secretion less viscid the following is indicated:

℞.	Ammon. chloridi	℥ii	8
	Syr. pulveris doveri	℥i	30
	Syr. senegæ q. s. ad	℥iv	120

M. Sig.: One teaspoonful every three hours.

In cases where Dover's powder proves too irritating to the stomach, an equal amount of tinctura opii camphorata may be substituted.

If the patients are feeble and require stimulating expectorants, the following is effective:

℞.	Ammon. carb.	℥ss	2
	Pulv. camphoræ	gr. xx	1 30

M. Ft. capsulæ No. x. Sig.: One every three hours.

Or if the patient can not swallow a capsule the following:

℞.	Ammon. carb.	gr. lxxx	5
	Aq. camphoræ		
	Syr. senegæ, āā	℥ii	60

M. Sig.: One dessertspoonful every three hours.

In the convalescing stage of acute bronchitis potassium iodid is of value combined with expectorants as follows:

℞.	Pot. iodidi	℥ii	8
	Syr. pulv. doveri	℥i	30
	Syr. pruni virg. q. s. ad	℥iv	120

M. Sig.: One teaspoonful every three hours.

Gastroptosis.

According to A. P. Francine, in *Phil. Med. Jour.*, the indications for treatment of gastroptosis are: 1. To relieve the stagnation and fermentation and to increase the motor power of the stomach. 2. To furnish support to the stomach and other abdominal viscera. 3. To improve the general condition of the patient. These may be accomplished by means of hygiene, diet, lavage, and drugs. The drugs which will be found of greatest service are resorcin, carbolic acid, creosote, aromatic spirits of ammonia and sodium bicarbonate.

The following combinations of the foregoing preparations have been used advantageously by the author:

℞.	Tinct. nucis vom.	℥vi	24
	Resorcin resublim.	℥i	4
	Tinct. cinchonæ co.	℥iiss	10

M. Sig.: Ten to fifteen drops every two hours; or:

℞.	Resorcin resublim.		
	Bismuthi subnit., āā	℥iiss	10
	Sodii bicarb.		
	Sacch. albi, āā	℥ii	8

M. Sig.: One teaspoonful every two hours; or:

℞.	Creosoti (beechwood)	gr. vii	35
	Sodii bicarb.	℥ii	8
	Pulv. acaciæ		
	Sacchari, āā, q. s.		
	Spts. lavendulæ co.	℥ii	8
	Aquæ q. s. ad	℥iii	90

M. Sig.: One teaspoonful after meals.; or:

℞.	Acidi carbol.	gtts. vi	35
	Sodii bicarb.	℥ii	8
	Spts. ammon. arom.	℥iv	16
	Spts. chloroformi	℥ii	8
	Mist. sodæ et menthæ	℥iii	90

M. Sig.: One teaspoonful after each meal and at bedtime.

Where there is nausea and vomiting the following does good:

℞.	Bismuthi salicylatis		
	Pepsini, āā	℥ii	8
	Cocainæ hydrochlor.	gr. i	06
	Aq. cinnamomi	℥iii	90

M. Sig.: One teaspoonful three times a day or more frequently if necessary.

Beer Yeast.

The *Medical Press*, in an abstract on the properties of yeast as a microbicide in certain eruptive affections as furunculosis,

chicken-pox, erysipelas, etc., states that very satisfactory results have been obtained. In eight cases of smallpox treated by Dr. Conche of Lyons the fever rapidly fell and the eruption did not come to maturity, consequently there was no suppuration. He administered the fresh beer yeast in beer, in order to mask the taste, giving three tablespoonfuls daily. Reports are also given where beer yeast was given in the treatment of erysipelas in doses of three teaspoonfuls daily. It was ascertained, under its influence, that the fever rapidly diminished and the area of inflammation did not enlarge. It was employed successfully also in the treatment of pneumonia and chronic bronchitis in the aged. In the bronchial catarrhs of old people the expectoration gradually decreased.

This periodical recommends the dry form prepared by chemists as more agreeable to take and as fully efficient as the fresh yeast.

To Cleanse the Scalp.

The following combination is recommended by the *West. Druggist* to relieve the scalp from dandruff:

℞. Olei ricini		
Aq. ammon.		
Am. carb., āā	℥i	4
Alcoholis	℥iv	120
Aquæ q. s. ad	℥viii	240

M. Dissolve the oil in the alcohol, add the ammonia water, and add the ammonium carbonate dissolved in the water.

Medicolegal.

Physician May Refresh Memory from Memorandum.—The United States Circuit Court of Appeals, Eighth Circuit, holds, in the case of Bailey vs. Warner, that a physician called to testify concerning a patient's physical condition at a certain time may be allowed to refresh his memory as to the patient's then condition, by consulting a memorandum which he made at the time of his visit relative to the patient's condition.

Time Texas Act Took Effect—Recording Under Old Law.—The Court of Civil Appeals of Texas holds, in Wickes-Nease vs. Watts, that the medical practice act of that state of Feb. 22, 1901, did not go into effect until 90 days after the legislature adjourned on April 9, 1901. The reason given is that the act did not contain any direction when it should go into effect, without which, in view of the constitution, it could not go into effect until 90 days after adjournment. It recited, "The fact that there is no law in force adequately providing for the license of physicians, surgeons and midwives creates an emergency and an imperative public necessity that the constitutional rule requiring bills to be read on three several days be suspended and this act placed on its final passage and it is so enacted." But the court sees in this no more than a suspension of the rules regarding the reading of bills. It also holds here that one who had been duly examined, in 1882, and given a certificate of qualification, which he had recorded in the office of the county clerk, but which he had never filed or recorded in the office of the clerk of the district court, as required by the act of March 23, 1887, could not recover for professional services rendered in May, 1901.

Salary of Health Officer that Was Fixed in Advance.—The Supreme Court of Mississippi affirms a judgment, in the case of Perkins vs. Panola County, allowing the party suing but $50 per annum as county health officer. The office had previously paid $300 per annum, but, prior to his appointment, the board of supervisors had fixed the salary at $50. Immediately after his appointment, he notified the board that he would not serve for $50 per annum, and subsequently resigned, but his resignation was not accepted by the State Board of Health, and he continued in office, notifying the board of supervisors that at the end of his term he would sue for a reasonable salary. The Supreme Court says that the verdict of the jury in favor of the county was a finding, on the whole evidence, that the reduction of the salary from $300 to $50 per annum was not, under the circumstances of this case, an abolition of the office. This salary was fixed in advance, as the law requires. The party suing was not appointed until after this. He acted in full view of the whole situation. On the facts in this record, no other proper result could have been reached than that arrived at by the jury.

Privilege Under Utah Statute.—Section 3,414 of the Revised Statutes of Utah provides: "There are particular relations in which it is the policy of the law to encourage confidence and to preserve it inviolate; therefore, a person can not be examined as a witness in the following cases: . . . (4) A physician or surgeon can not, without the consent of his patient, be examined in a civil action as to any information acquired in attending the patient, which was necessary to enable him to prescribe or act for the patient." The Supreme Court of Utah says, in the personal injury case of Munz vs. The Salt Lake City Railroad Company, that the policy of this law is to keep inviolate the secrets of those who are in charge of physicians, and to encourage confidence between physician and patient. Whether the statute is a wise or unwise enactment is not for the courts to decide. It is their province to give it such a reasonable interpretation as will give effect to the legislative will. Its evident purpose is to prevent a physician from disclosing information obtained in the sick room necessary to properly discharge his professional duties to the patient, and this is so as to any such information, whether obtained directly from the lips of the patient, or from observation, or from those present at the time of the examination. Nor is it material in such that the physician was called by the patient or a stranger, or, as in this instance, by an officer of the company sued, at the request of the patient. In general, whenever such an examination is made, the presumption is that the relation of physician and patient exists, and that the information is obtained for the purpose of enabling the physician to prescribe or act for the patient. In this case, the injured party testified that they had no money to pay a doctor; that she went to see the company's superintendent about her injury, and that he sent the physician. The physician stated that he examined the patient at her home by request of an official of the company; that he was at liberty to prescribe treatment; that, if he had found a condition that needed treatment, he would have prescribed; that he did prescribe and treat such cases where they required it; and that one of the conditions in view when the examination was made was to prescribe, if necessary. The court holds that the testimony of the physician as to what such examination revealed was properly excluded. It says that the physician made the examination with the view of prescribing if the condition of the patient required it, and under the circumstances disclosed in the evidence it was clear that the relation of physician and patient existed, and the information thus obtained was privileged under the statute.

Compensation of Surgeon—Opinions—Raising Bill.—In the case of Ladd vs. Witte, an action brought to recover for services in performing an operation on the latter party's newly-born imperfect child, the Supreme Court of Wisconsin holds that an instruction telling the jury that they must determine the value of the services, under all the credible evidence in the case, if they should be of the opinion that the services were of value to the party sued, was based on a most unfortunate and misleading hypothesis. It says that it certainly tended to confine the jury to consideration of what and how much benefit resulted to the party sued from this fruitless incision into the body of his new-born child, whose death was certain without the operation, but equally occurred, it notwithstanding. That is not at all the test. So that a surgical operation be conceived and performed with due skill and care, the price to be paid therefor does not depend on the result. The event so generally lies with the forces of Nature that all intelligent men know and understand that the surgeon is not responsible therefor. In absence of express agreement, the surgeon who brings to such a service due skill and care earns the reasonable and customary price therefor, whether the outcome be beneficial to the patient or the reverse. The surgeon requested a direct and plain instruction that the jury must be guided solely by the evidence relating to the value of services. It was error to incumber such direction by the hypothesis stated. Again, the jury were instructed that the opinions of experts as to the

value of the services of the surgeon were not conclusive on them. Such opinions were advisory only. They must, in the end, use their own judgment in determining the value of the services, guided by the credible evidence in the case, and assisted by opinions of the experts. This instruction the court also holds erroneous, there being no evidence whatever in conflict with that of the two physicians—one disinterested—that, in their opinion, the customary and reasonable value of the services rendered exceeded $50. In the absence of conflicting evidentiary facts, it says that there seems to be no answer to the logic that jurymen, as such, have no presumptive knowledge on the subject of the value of professional services, and must be guided by the evidence offered on the trial, and consequently are not at liberty to disregard the same, and enter the field of their own uninstructed conjecture. An instruction to the effect that the surgeon was not precluded from recovering more by reason of having originally sent his bill for but $50, the court says would, of course, have correctly stated the law, and might well have been given to assure full understanding by the jury, though, technically, it was covered by an instruction to allow such sum as the evidence proved the value of the services to be up to $100, the amount of the surgeon's amended claim.

5 Remarks on Bacteriology and Serum Treatment of Puerperal Septicemia, with an Illustrative Case. Charles S. White.

1. **Hospital Treatment.**—The four diseases, the treatment of which in the Presbyterian, Roosevelt, New York and Bellevue hospitals is described, are, first, typhoid fever, which is treated by an exclusive milk diet, alcoholic and other stimulants, the Brandt bath treatment; the special symptoms such as headache, sleeplessness, etc., being properly met and the patient kept in bed until after the temperature has been normal for a week. In the second disease, pneumonia, the treatment begins with calomel in small doses followed by a saline, the calomel repeated during the course of the disease, if necessary. Local measures are applied as required. The treatment of fever varies. The plan of water treatment is not uniformly applied. Some tub patients with a temperature of 103 and over, and some use sponging when it reaches 102. For the severe pain, poultices and hypodermics of morphin are employed. At the Roosevelt Hospital they often strap the side instead of poulticing. For insomnia the one drug which is universally used is codein in ¼-gr. doses. The three cardiac stimulants used in all the hospitals are alcohol, strychnin and digitalis; the latter only when the others have failed, as a rule. The only other drug occasionally used by all four was nitro-glycerin, and cyanosis is the one symptom which specially indicates its use. For acute articular rheumatism the alkaline salicylate treatment seems to be generally employed. Oil of wintergreen is used to a certain extent in some of the hospitals. At the Roosevelt Hospital the salicylate treatment is first tried, and if not effective, the alkaline treatment follows. Guaiacol is employed in all the hospitals except the Roosevelt, largely by applying it directly to the joint. The diet in all is the same, exclusively milk. Hyperpyrexia is treated in the New York and Presbyterian hospitals by tubs for a temperature of over 105. Pericarditis is treated at all by ice-bags at the precardial space and morphin, if required. The fourth ailment is pleurisy with effusion, and in only one of the hospitals is the fluid removed from the chest when the condition is first diagnosed. In all the others the case is watched before aspiration, and operation is performed only in case of a large amount of fluid, pain, and embarrassed heart action and prostration, and when the fluid remains at a fixed level for five or ten days. The methods vary a little in the different institutions. The following indications for operation are recognized by all, cardiac embarrassment, severe pain, persistent cough and faintness. The diet is what is known as soft, eggs, gruel, soups and principally milk.

3. **Adhesive Plaster Strapping.**—The different pathologic conditions which call for this measure, according to Cook, possess one factor in common, relaxation of tissue, and he points out its special advantages in sprains and contusions. The ordinary diagnosis of sprain is inadequate. We should know exactly what particular ligament or ligaments are involved, and where a ligament has more than one insertion, it is our duty to ascertain what special part is the seat of the sprain, and adopt measures accordingly. He reports a number of cases.

4. **Inguino-Superficial Hernia (Kuester).**—A case is reported by Moschcowitz, who discusses the pathology. In this case there was originally a cryptorchidism and open processus vaginalis. Only the omentum was involved. He reviews the literature and explains the mechanism.

9 Plague Serum in Three Cases. W. J. Calvert.
10 The General Treatment of Tubercular Bone and Joint Diseases. Joel E. Goldthwait.

6. **Joint Tuberculosis.**—From a total of 47 observations and the study of the literature Painter draws the following conclusions:

1. Tuberculous disease tends to recur after apparent cure in a considerable proportion of cases.
2. This recurrence is most commonly a local one. Metastases are not common.
3. Trauma, direct or indirect, is frequently associated with the recurrence. Indirect trauma is probably the exciting cause of the recurrences, especially where partial anchylosis or deformity exists.
4. Patients who have suffered from bone and joint tuberculosis should be cautioned that they are not well when symptoms have ceased and that reasonable care must be exercised to avoid recrudescences.
5. Deformity and shortening should be corrected as far and as accurately as possible to lessen the chance of recrudescence.
6. Mechanical treatment, especially fixation, should be used in the acute conditions in childhood. Exploratory interference, where discretion is used, with a view to removal of isolated foci, is *advisable* in many cases in children, and is to be *urged* in the majority of the recrudescences, if seen early. Recognition of the fact that patients with hip disease, Pott's disease and tumor albus have tuberculosis just as much as if they had phthisis, and should be treated accordingly, must be insisted upon.

7. **Measles.**—McCollom finds that measles is not such a mild disease as commonly held, and hospital treatment is advisable. It is the most infectious of all disorders and may be so long before the diagnosis. Its complications are serious, especially diphtheria, and its sequelæ, like inflammation of the ear, are also liable to give trouble. There are many individuals living in boarding houses or lodging houses who require hospital treatment if attacked by this disease, and present accommodations are inadequate. A separate pavilion is absolutely necessary for the treatment of these patients in a hospital.

8. **Downes' Electrothermic Angiotribe.**—Keefe has experimented on animals by resection of the intestine with the aid of this instrument, and reports results. He also reports a number of gynecologic cases in which it was also utilized. In none of the cases were ligatures used, and no hemorrhages occurred. The advantages are rapidity of operation, asepsis and cleanliness, no soiling with blood, pus or feces, hemostasis without the aid of a ligature, no secondary hemorrhage from the splitting of ligatures, or subsequent infection of the same, less pain subsequent to operation as the tissues are not puckered or constricted by ligatures. The use of the instrument is very simple, and it should be tried before passing judgment on it.

16 *Treatment of Malignant Growths with the X-Rays. William S. Newcomet.
17 *Urine Segregation; Its Importance and Methods. Andrew J. Downes.

11. **Health Resorts of New Zealand.**—Lydston gives a very interesting account of the health resorts in New Zealand, which seems to be a country specially endowed in this respect. A special series of articles on the Doctor's travels are appearing in THE JOURNAL A. M. A.

12. **Carcinoma Uteri.**—Montgomery's article points out the connections between parturition injuries and cervical carcinoma and insists on preventive measures. The exploration of injuries to the pelvic floor and cervix, especially near the menopause, antiseptic local treatment, and the general necessity of early recognition of the condition and early operation in healthy tissue, with care to prevent reimplantation of the diseases, are insisted on. In the majority of cases the abdominal method is preferable to the vaginal, as it enables one to get farther away from the involved structures.

13. **Parasyphilitic Affections.**—The history of parasyphilitic disorders and Fournier's part in its origination is noticed by Leredde, who disagrees with Fournier, holding that the term has been made to cover too wide a signification and that we should broaden our ideas of what is really syphilitic. What we call parasyphilitic disorders are probably really syphilis in their pathology.

14. **Visceral Ptoses.**—Taylor gives the treatment of visceral ptoses which he would advise, consisting in stomach lavage, faradization, exercise, improved attitude in standing, and disuse of belts, as a rule, excepting one which he has found of advantage, the device of Morris Longstreth of Philadelphia, which is non-elastic, firm, and holds the abdomen in its proper place. The danger is that it is liable to over-use. The real curative agency is a series of exercises which he describes to strengthen the abdominal walls and other muscles that are involved, such as the diaphragm and intercostals. They consist in stretching movements of the limbs, ligaments, abdomen, hips, etc., that gradually push the tissues back into place, but so slowly that no harm can be done. For details the reader is referred to the original article.

15. **Actinotherapy.**—Gottheil's article is a review of the various disorders in which this method has been proven of advantage.

16. **X-Rays.**—Newcomet reports several cases of carcinoma and epithelioma cured or relieved by the *x*-ray.

17. **Urine Segregation.**—Downes describes a new instrument, a modification of and improvement on the Harris segregator, being simpler in structure and requiring no suction apparatus, and introducing a new feature, siphonage, for obtaining the urine from a divided bladder. In the later form the urine at all levels is conducted to the bottom of the prepared sulcus, from which it is siphoned out. It is not, however, as efficient in the female as in the male bladder, and he has, therefore, made a shorter instrument for use in the female bladder alone.

23 Intermenstrual Pain. Jennie G. Drennan.

18.—See abstract in THE JOURNAL, Dec. 20, 1902, p. 1609.

19. **Medical Teaching.**—Thompson points out certain difficulties in clinical teaching, the difficulty of handling every variety of the disease, of demonstrating all the symptoms of any given one, and the danger of bedside teaching becoming too superficial. In pointing out the difficulties he does not intend to disparage the method, but thinks it should be employed to elucidate rather than to supersede the broad foundation laid by reading and recitations, and supplemented by didactic and clinical lectures. See also THE JOURNAL, Dec. 20, 1902, p. 1610.

20. **Sterilization of Catheters.**—Nancrede and Hutchings give a report of their experiments to test the value of boiling in sterilizing catheters. They find the elastic (that is the English-web catheters) and soft-rubber catheters can be repeatedly boiled for five or more minutes without roughening of their surfaces or diminution of their elasticity and strength. Chemical sterilization requires a longer period, as does also formalin vapor. Just how short a time with the latter will be efficient they propose to ascertain. All the methods of sterilization commonly employed should be continued for a longer period than the minimum required for laboratory germ destruction. Washing with warm soapsuds is not essential. Boiling carries away the oily lubricants that have been used, together with many germs. In boiling the catheter it is necessary to keep it from touching the bottom of the vessel, which can be done by enveloping it in gauze or a towel. Their experiments are given in detail.

21. **Veratrum Viride.**—Isham reports cases treated by subcutaneous injections of veratrum viride, of eclampsia, pneumococcus infection, tuberculosis, convulsions, gallstone disease, acute delirium, etc. He holds that with veratrum viride dehydration of the tissues and the renewed and purified blood stream, furnishes a means for regeneration. He thinks that it can be used in tetanus or strychnia poisoning. The properties by which it acts are largely inherent in its active principles of jervia and veratroidia. He speaks also of the value of the moral effect of the remedy, which is very decided. He uses it in hypodermic injections in 10 to 15 minims of Norwood's tincture and even larger doses. He says he thinks 20 drops of Norwood's tincture is the proper initial dose in the adult, to be followed by 10 drops more in half an hour where it falls short of emesis. In no case have fatal effects followed the medication.

22. **Joint Disease.**—Stolper points out:

1. That no matter how bad or how far the disease of the joint may have progressed, with our present methods the sufferer can expect not only relief, but positive curative effects if proper steps of treatment are adopted. 2. That while we have no general plan for the treatment of such cases, we have by the aspirating needle and microscope a valuable uniform plan for diagnosis. 3. That diseases of the joints being due to many causes, the systemic conditions, family and personal history of the patient become of the utmost importance. 4. That my method of treatment is a modified Phelps' method, but superior to Phelps' in the following points: (*a*) Carbolic acid, if used in drop doses only, does not have the desired effect; in large doses it causes sloughing of the parts, while bichlorid of mercury, if not allowed to be absorbed, accomplishes its purpose and can be used in any quantity; (*b*) the 1 to 2,000 solution, while not too strong, is strong enough for germicidal purposes; (*c*) the use of alcohol hardens the tissues and prevents the absorption of the mercury, which is washed out with sterilized water. 5. That while I know that it is the practice of the profession to condemn operations on tuberculous joints, I wish to urge the advisability and necessity of such operations. Let us treat tuberculous conditions, when possible, as any other septic condition.

24 *The Treatment of Epilepsy by the General Practitioner. William P. Spratling.
25 Report of Two Cases of Transverse Position of the Fetus with Prolapse of an Arm and Impaction. Charles S. Barnes.
26 *Gastrosia Fungosa. Mark I. Knapp.
27 The Causes of Death in Diphtheria. Bernard Kohn.
28 *Pertussis, with Special Reference to Its Early Diagnosis from the Blood Findings. Alfred Wanstall.
29 A Case of Infection with the Double-Pored Dog Tapeworm (Diplyidium caninum) in an American Child. Ch. Wardell Stiles.
30 Hospital Work of Dr. Carl Lauenstein. Nicholas Senn.

24. **Epilepsy.**—Spratling maintains that epilepsy is curable in many instances. Its two primary causes are heredity and stress, heredity, similar and dissimilar, existing in some 56 per cent. of cases. Among the commoner forms of stress, as he calls it, are menstrual derangement, syphilis, alcoholism, etc. He says there are to-day in the Craig Colony a number of epileptics who have no convulsions whatever because they can get no alcohol. Among the more active causes in early life and in infancy, he mentions the accidents at birth, such as asphyxia of the newborn, emphasized by Dr. Jacobi, and blood clots occurring at birth. As regards treatment, he insists on

individualizing, necessitating a regulated dietary, and if the bromids are used, the deprivation of salt, correction of optical defects, gastrointestinal disorders, etc.

26. **Gastrosia Fungosa.**—This is supplementary to a monograph on organacidia gastrica, published in the *New York Medical Record*, Sept. 6, 1902. Knapp describes the symptoms of mold in the stomach, pointing out the methods of diagnosis, and the therapeutic principles of cleaning out the mold, and giving drugs to destroy the organic acids. Lavage, the use of mineral acids, the use of fresh-cooked food, the thorough washing of vegetables and fruits, especially grapes, are also mentioned. He reports and discusses cases.

28. **Pertussis.**—The special point of Wanstall's paper is the blood examination. The excess of lymphocytes over polynuclear neutrophiles is rather characteristic of this disorder. Figures, however, are more convincing *en masse* than when considered individually, and exceptions to the rule may be found.

36 *Thoughts on Fetal Intracranial Hemorrhage. Douglas H. Stewart.
37 *Note on the Salt Starvation Principle in Epilepsy Treatment by Bromids. L. Pierce Clark.

31. **The Colorado Climate.**—The natural advantages of Colorado, the mildness of its climate, abundance of pure air and sunshine and natural sanitary conditions are first noted, and after these the acquired advantages. The author points out how the pulmonary patient may be improved in this locality better than elsewhere. One of the greatest misfortunes is that there is no adequate regulation of quacks, but if the patient puts himself in the hands of a reliable physician, much can be done.

32.—See abstract in THE JOURNAL, xxxix, p. 1,204.

33. **Chorioepithelioma.**—Bandler explains chorioepithelioma according to an elaborate theory of his own, namely, that it is due to an overgrowth of fetal cells which are constantly entering the organism of the mother. The ovarian influence which should hold overgrowth in check is not sufficient. His theory includes an explanation of fecundation, pregnancy and labor. The ovary is responsible for the changes which show themselves in the periodic loss of blood known as menstruation, but if a fecundated ovum is present, the ovum and its enzymes nullify the menstrual stimulation of the ovarian secretion. The trophoblast cells invade the maternal decidua, which is now constantly stimulated by the ovarian secretion, and likewise enter the blood of the mother. The placental secretion nullifies the action of the usual forces and menstruation does not occur. At the end of nine months, when the ovarian secretion is sufficient in amount or character to overcome the neutralizing action of the enzymes of the ovum, labor occurs. If between fecundation and parturition the ovarian secretion is in excess, the constitutional involvement known as eclampsia results. The occurrence of chorioepithelioma is due to a lack of some normal secretion, which he thinks is probably an ovarian secretion that is sufficient to hold the growth of fetal cells in check.

34. **Tonsil Affections.**—Faulkner's article is rather a general one, describing the tonsils and their probable functions and holding that wisdom seems to demand in every case of tonsillar affection, thorough antiseptics, greater care in the preservation of lymphoid structure, and more conservative surgical and decidedly more comprehensive and detailed medical treatment of the nares.

35. **Vaccination Tetanus.**—Cooke reports a case in a four-year-old child with favorable termination, which he thinks was due to post-vaccinal infection during the child's play out of doors.

36. **Fetal Intracranial Hemorrhage.**—The idea Stewart advances is that this accident arises from unequal squeezing of the cranium and its contents. He thinks much can be done to prevent it by careful dilation of the os and pressure with rubber dilator in case of dry labor, and proper forceps manipulation to put the head in a position where undue intracranial pressure will be avoided. When the child is born, feel the fontanelles with the palmar surface of the finger, never with the point, having the contact as extensive as possible; pulsations are made out quite clearly in this manner. Lay the palmar surface of the little finger along the arched top of the tongue, and if there is tremor or rigidity the clot is at the base. There is no attempt at sucking. There may or may not be in the vertex cases, although sucking well on the second or third day is no disproof. Rigidity of the jaw is rare. A peculiar convergent strabismus (clonic) is common, and gives good ground for a fatal prognosis if it lasts more than a few minutes. It is also found after burns in infants, and if it begins, usually continues until death.

37. **Epilepsy.**—Clark calls attention to the importance of hypochlorization in epilepsy, reducing the sum total of chlorin in the body and making room for bromids. This, of course, does not obviate the necessity of other measures, hydrotherapy, massage and general hygienic treatment, but does away with bromism, gastric irritation, constipation and mental hebetude common in the older forms of bromid sedation. A lesser quantity of bromid is needed.

42 *Overenthusiasm and "Fake" Specialism in the Diagnosis and Treatment of Genito-Urinary Disease. G. Frank Lydston.
43 *Observations on the Treatment of Malaria. Virginius W. Gayle.

41. **Eyestrain of Children.**—Eggers' article was read before a teachers' institute and gives the facts as to the importance of care of the eyesight in children and the means of avoiding injury at an early age in school studies and methods.

42. **Specialism in Genito-Urinary Disease.**—Lydston protests against the too vigorous methods of treatment of cases of genito-urinary disease, illustrating it by cases from which he deduces the following:

1. That unnecessary manipulations and explorations of the genito-urinary organs are dangerous. 2. That the long way around to diagnoses should be avoided when the short cut by the common-sense road is sufficient. 3. That preliminary "accurate" diagnostic explorations, especially under anesthesia, should be avoided where practicable, and operations which have been proven necessary at once proceeded with.

He remarks also that he has seen a number of cases where fatal results followed radical operations on the genito-urinary organs and in which he felt that the double exposure to anesthesia in the preliminary diagnosis and during the operation, rather than the latter *per se*, was responsible for the death of the patient.

43. **Malaria.**—Gayle's article recommends the salicylic acid ester of quinin, known as saloquinin, as being free from the objections to quinin in malaria and a perfect substitute for it. It is tasteless, non-toxic, does not produce nervous disturbance, mental distress or tinnitus, while it is analgesic, antipyretic, and its action as a germicide is greater than quinin. Idiosynerasy need not be considered, as no bad effects follow its use. It is a remedy, he says, to use in malarial hematuria, can be given to pregnant women because it has no oxytocic effects, and is also beneficial in la grippe.

50 Paraffin Injection in a Case of Deformed Nose. W. A. Porteous.
51 *A Few Thoughts on Rheumatism Other Than the Acute Articular Form. G. F. Smith.

44. **Malignant Disease of the Gall Bladder.**—Out of 405 operations performed on the gall bladder and biliary passages in St. Mary's Hospital Rochester, Minn., during ten years, nearly 5 per cent. were of the malignant type, a frequency which Mayo remarks is sufficient to deserve careful attention. It seems to be much more prevalent in females than in males. Its connection with gallstones is noted. He says the following indisputable facts attract attention: 1. Gallstones are almost constantly present in primary malignant disease of the gall bladder and rarely in secondary. 2. The relative proportion of gallstones and malignant disease of the gall bladder in women and men is practically identical. 3. The pathologic lesions found are best explainable on this theory. 4. The similarity in age frequency. These, he thinks, warrant the opinion that gallstones are an important etiologic factor in malignant disease of this organ. The diagnosis is usually easy, though there may be some confusion with cyst of the gall bladder and stone impacted in the cystic duct, or adherent gall bladder shrunken down on a mass of stone. It is sometimes impossible even on the operating table to say whether a thick-walled gall bladder is malignant or not. Mayo reports in conclusion several cases and remarks that in all cases where the liver was involved secondary to primary cancer of the gall bladder, there was early recurrence. This is also true in those cases in which the lymphatic glands in the tissue of the liver were infected. Jaundice occurs in about one-half of the cases and contraindicates operation, as it is a late symptom.

45. **Pneumonia.**—Tomlinson reviews pneumonia in its relation to other organs than the lungs, calling attention to the variation in symptoms in certain cases, remarking that it should be considered more a general toxemia than as a local lung disease. Autointoxication, gastrointestinal in origin, and failure of elimination, due to renal inadequacy, are in his experience the gravest dangers.

47. **Gastric Ulcer.**—Graham describes the symptoms of gastric ulcer, gas, belching or bloating or both, burning pain, eructations, heart burn, sour stomach, vomiting, weakness and hemorrhage. The more characteristic and common symptoms, such as pain and vomiting, are treated of at length. The difference between the characteristic symptoms of cancer where there is a more constant and diffuse pain, and gallstones are remarked. In conclusion he mentions gastrosuccorrhea of nervous origin and gastralgia as causing possible conditions embarrassing the diagnosis.

48. **Methylene Blue.**—Drenning holds that methylene blue is practically non-active in gonorrhea and reports cases to prove his contention. Its psychologic effect, however, renders it still a popular method. There is nothing that produces such prominent obvious effect to the patient with so little inconvenience.

51. **Rheumatism.**—Smith advocates aspirin in rheumatism as relieving pain and inconvenience and gives cases where he has found it of benefit. It is a potent agent, he says, especially where the salicylates have proven inefficient, and in chronic, subacute and abarticular forms of rheumatism.

56 *Liquefied Oxygen and X-Ray Treatment of Malignant Growths. A. Campbell White.
57 Report of a Case of Syringomyelia. M. W. Hoge.

52. **Defective Bladder Drainage.**—Defective natural drainage is rare in childhood and early life owing to the anatomical conditions, but later becomes not uncommon, especially after the 60th year in the male, with incontinence from bladder irritation or inflammation, possibly the formation of phosphatic stone, possible extravasation of urine, etc. The bladder may sometimes, by reason of decomposing urine in its effect, resemble, so far as its contents are concerned, a chronic abscess. In such cases catheter drainage and thorough washing out fails to supply that free and continuous drainage that is required. Harrison mentions his method of urine drainage by the perineum, puncturing the membranous urethra on the centrally-grooved staff sufficient to permit the introduction of a finger in the bladder, followed by a drainage tube made to fit correctly both in length and in relation to surrounding tissues, without side leakage. For the first forty-eight hours a specially-made gum-elastic tube should be used, later one of Annandale's pattern with a drainage continuation and tap is substituted. In this way the patient may be up and about within a few days, wearing his apparatus, and long confinement is avoided. In some instances drainage soon proves effectual in restoring the natural condition, while in others the permanent utility of the apparatus may render life comparatively comfortable. Catheter life, he thinks, is not warranted by slight inconvenience and urination once or twice at night and corresponding calls in the day time. Considerable discretion, however, must be exercised on this point. For decomposition of residual urine, which sometimes is not relieved by catheter and lavage, he suggests the use of urotropin, benzoate of ammonium and salol.

53. **X-Ray Protection.**—Pusey finds sheet lead the best protective; 1/25 of an inch thick is usually sufficient to exclude the *x*-rays. He covers the masks on both sides with ordinary wrapping paper, which can easily be washed off and replaced, leaving the mask clean. A speculum can be made by the use of block-tin tubing. For vaginal exposure he has used the ordinary Ferguson specula. To make exposure in the mouth, vagina, or even the rectum, Caldwell's tube is by far the best method; in fact, this is, in his opinion, the greatest single addition that has been made to the technic of the therapeutics of the *x*-rays. The hard rubber masks that have been suggested, he thinks, are almost no protection. If for any reason it is impossible to use lead, some slight protection may be obtained from oxid of zinc adhesive plaster; equal parts of bismuth subnitrite and vaselin would make a fair protection. Vaselin of itself is absolutely useless.

54. **Fractures.**—Beck points out the value of the Roentgen ray in the detection of fractures and their necessary individual treatment.

55. **Bacillus Pestis.**—Calvert has experimented on the viability of this bacillus by preparing tubes which were placed in a thermostat, exposed to direct sunlight on hot pavements, etc. They showed that the *Bacillus pestis* is more resistant than has ordinarily been believed. If an organism can live forty-four days on paper in a thermostat, at 32 to 34 C., or two hours and 45 minutes on a hot brick pavement in the tropical sun at 130 to 140 F., it can certainly live longer in a moist, dark room, where more suitable culture materials can be found. In the Orient there are many out-door spots where the sun never shines, and here the bacilli might live for an indefinite time.

56. **Liquefied Oxygen.**—This substance, which is ordinarily called liquefied air, but which more properly becomes liquefied oxygen by the rapid evaporation of nitrogen, is considered in some cases preferable to the *x*-rays for the treatment of malignant disease. White would employ it in the treatment of superficial epithelioma, but exclude it in cancer of the breast where no ulceration has taken place. For ulceration, followed by hemorrhages and excessive odor, it is indicated, and it would be an excellent change from arsenic and other caustic measures used as an adjuvant to hasten matters.

62 *On the Use of Large Doses of Salicylate of Sodium and an Attempt to Explain Its Action. H. Gifford.
63 *On the Necessity for the Use of Color Names in a Test for Color Blindness. F. W. Edridge-Green.

60. **Heterophoria.**—In Black's last 1,000 refraction cases only 49 have been cases of heterophoria. Under this term he

includes only those where there is at least 5 degrees of lateral imbalance or 1 degree of vertical imbalance. Women are more frequent sufferers than men. He has been disappointed with all forms of exercise of the eye muscles for its correction, except in cases clearly dependent on constitutional conditions. Prisms up to 5 degrees for lateral correction and up to 3 degrees for vertical correction, are often worn for years with comfort, but he is inclined to think that in most cases to prescribe a prism of a given strength means that later one of a higher degree will be required, and so on until operation is demanded. This applies more to lateral than to vertical correction. The measurements of adduction, abduction and circumduction do not throw much additional light on the case. Tenotomy should be a last resort. He does not use any "graduating" on the tendon, in tenotomy, except where the vertical muscles are concerned: He prefers a little over-effect to under-effect.

62. **Salicylate of Sodium.**—Gifford thinks that salicylate of sodium is employed in too small doses in rheumatic eye complications. He has not had much good from aspirin. His views in regard to the use of the salicylate in sympathetic ophthalmia have already been published. In interstitial keratitis where the patient shows no marked signs of hereditary syphilis, it acts almost like a specific, and in iritis the relation between the condition and the rheumatic diathesis is best clearly shown by the effect of this drug. He has also found it useful in the pain of herpes of the cornea. As to the manner in which it acts he finds that very large doses can be borne. A man can take about one grain per pound weight in the waking hours, and it begins to be excreted almost immediately. Its germicidal action seems slight, but he favors Oltramare's idea that its effect is due to local depletion caused by general capillary dilatation which the salicylates induce.

63. **Color-Blindness.**—Edridge-Green insists on the necessity of using color names in color tests. A man must be able to think that a light is red before he can act on it, and it is just the same as if he had made the observation out loud. Without their use normal individuals may fail in these usual tests.

68 Report of a Case of Epilepsy, Treated by Electricity and Suggestion. B. Elizabeth Malone.
69 Guaiacol in Typhoid Fever. A. T. Stewart.

65. **Felon.**—Eastman calls attention to the treatment which he observed in Von Bergmann's Polyclinic in 1897, with alcohol and air exclusion. The method is simple. The involved phalanx should be covered with a thin layer of sterilized absorbent cotton saturated with alcohol. Over this a thin rubber fingerstall should be applied, rolled on itself from the open end toward the apex and applied over the cotton by unrolling. Of course, where there is suppuration and in severe septic cases, the tissues should be promptly and deeply incised, but in simple incipient cases incision may be not only unnecessary, but reprehensible. It is wise to avoid a tender scar on the palmar surface of the finger.

72 *A Case of Peripheral Abducens Palsy. Wendell Reber.
73 *Kleptomania and Collectivism. James G. Kiernan.

72. **Abducens Palsy.**—Reber reports a case which he says must be regarded as an instance of such palsy, if it exists. His experiences with other cases has led him to become skeptical as to the proper reference of these conditions as a true morbid entity.

73. **Kleptomania.**—Kiernan describes the condition of kleptomania, pointing out the temptation of the bargain stores to a certain class of morbid women, to whom the desire of acquisition of certain articles is absolutely without reference to profit. He thinks that in cases where kleptomania is pleaded, the question of mental instability should be thoroughly studied. There is no need for new legal principles, the common law properly interpreted is ample to meet the cases. He associates a sexual origin with these conditions in some cases, and this psychologic factor underlies some thieving during pregnancy.

79 A Case of Glanders in the Human Subject. H. A. L. Ryfkogel.

74. **Flat Foot.**—Watkins' article is an exceedingly elaborate discussion showing the pathology, causes and treatment of weak foot. To be properly utilized, it should be studied in the original, as it can not very well be satisfactorily abstracted.

76. **Intestinal Anastomosis.**—Huntington illustrates the Connell suture and knot within the lumen, and reports his experience. He considers it one of the best, if not the best method we have for intestinal anastomosis, and quotes Murphy in conclusion, who says that if suturing is to be used at all he believes the Connell suture has advantages over any other with which he is conversant.

78. **Kraurosis Ani.**—Fitch reports a case of this condition which has not been before noticed in this particular anatomical situation. It occurred in an adult Chinaman, and the only apparent cause for it was a slight debauch. He has seen a case where both the vulva and anus were involved together, but none before in which the anus alone was implicated.

80 *Some Unusual Phenomena Observed in Three Typhoid Cases. H. L. Sutherland.
81 The State Board of Health: Its Opportunity. H. M. Folkes.

80. **Typhoid.**—Three cases with unusual symptoms are reported by Sutherland. In one there were convulsions, and after apparent improvement a repetition ending in death. The temperature range was not high. There was no serious bowel lesion. The characteristic symptoms of meningitis were not in evidence. Tetany was present for a time, but it is not generally serious. The diagnosis of typhoid was by the Widal reaction. In the second case there was, with atypical symptoms of typhoid, the normal occurrence of the menstrual period, which is unusual. In the third case there were unusual symptoms of temporary mental aberration. The patient's temperature was only once up to 100. He thinks we should be especially careful where there is any possibility of typhoid fever to avoid the diagnosis of insanity, which may be simulated by the delirium of the disease, while other symptoms are not very marked.

82 *Sequelæ of Typhoid Fever as Related to the Eye, with Special Reference to the Accommodation. George H. Price.

82. **Eye Lesions of Typhoid.**—Price reports cases with comments on the accommodation disorders following typhoid. He discusses the subject at length, quoting largely from Nichols' work published in the *Journal of Experimental Medicine* of 1899, and holds with him that the trouble is primarily a neuritis due to toxins acting on the neurons and motor region of the spinal cord. The principal means of combating the condition, he holds, lies in preventive measures, and some internal drugs during the progress of the disease that will prevent its complications. During convalescence he suggests that patients refrain from anything that would add to the nervous strain or tax the muscular mechanism until it is able to stand the strain.

83 *The Pathology of the Tissue Changes Induced by the X-Ray. A. G. Ellis.

84 A Preliminary Report upon the Simulation of Aneurism by Atheroma and Tortuosity of the Arch of the Aorta. Joseph Sailer and G. E. Pfahler.
85 Pyloric Carcinoma, with Symptoms Simulating Gastrocolic Fistula. D. L. Edsall and C. A. Fife.
86 Round Worms (Ascaris Lumbricoides) from a Patient with Typhoid Fever. David Riesman.

83. **X-Ray Tissue Changes.**—This article, which is of the nature of a preliminary report, first notes the observations of others and their opinions in regard to tissue changes from the *x*-rays and then reports four cases which were carefully examined. Ellis finds necrosis of cells and trabeculæ of a varying degree. In Case 1 there is also marked fatty degeneration. In three cases there was increase of elastic tissue before and after exposure. In one case there were fewer areas of lymphocytic infiltration after exposure, and about equal numbers before and after in others. A tendency to occlusion of vessels by deposits on their inner surfaces, marked in some cases. Practically entire absence of infiltration of polymorphonuclear leucocytes. These findings, he remarks, do not hardly warrant conclusions, but a few thoughts suggest themselves. The blood vessel changes, on which Beck and others lay stress, seem hardly to account for the accompanying tissue necrosis, though endarteritis is probably induced by the *x*-ray. He thinks the possibility is suggested of their being similar lesions from the same influence instead of standing in relation of cause and effect. The presence of immense number of cocci and bacilli in the tissues in one case after twenty exposures of the *x*-ray would argue against the bactericidal power of the ray. It should be said, however, that the pathogenicity of these organisms was not proven. The unsatisfactory clinical results, as well as the slight microscopic changes in Case 3 can probably be attributed to the extremely numerous keratinized areas or "pearls." This emphasizes the importance of curetting or cutting away diseased tissue, whenever feasible, before using the *x*-ray.

87 *Surgical Treatment of Hemorrhagic Pachymeningitis. John C. Munro.
88 *The Gravity of Bronchitis in Elderly Men and the Safety-Valve Action of Relative Tricuspid Insufficiency, with Report of a Case. Robert H. Babcock.
89 *Albugineotomy in Chronic Orchitis with Report of Case. Emanuel J. Senn.
90 *Report of a Case of Ventral Fixation, Pregnancy, Invagination of the Uterus, Death and Autopsy. Wm. E. Holland and Byron Robinson.
91 *X-Ray Tube, Shields, and Specula for Treating Cancer of the Rectum and Other Cavities. J. Rawson Pennington.
92 *The Relation of Gonorrhea to Tuberculosis of the Genito-urinary Tract. Daniel N. Eisendrath.
93 A Case of Early Rupture of Tubal Pregnancy. Henry Banga.
94 Doctors' Business Methods and the Collection of Their Accounts. C. F. Meyer.

87. **Hemorrhagic Pachymeningitis.**—Munro analyzes cases from a recent record of the Boston City Hospital and discusses the disorder. The difficulties of diagnosis, especially of getting histories, are noted, and its relation to trauma, syphilis, etc. Trephining, he thinks, is the only method to be considered. The prognosis is not good at best. The following are his conclusions:

1. Hemorrhagic pachymeningitis is found in the insane and in infants, but for the most part in men not insane after middle life.
2. Alcohol, syphilis, acute and wasting diseases, and trauma apparently bear some causative relation.
3. The symptoms are those of diffuse subdural hemorrhage, coming on slowly, producing mental irritation, spasm and rigidity of the extremities, convulsions, and, later, paralysis, the sequence being more or less irregular.
4. The cranial nerves are not liable to be affected.
5. The treatment is surgical, and should be instituted as early in the disease as possible.
6. Without operative relief in cases with pressure symptoms the prognosis is practically hopeless. Early operation is not serious and gives the best chance of recovery.

88.—See abstract in THE JOURNAL, xxxix, p. 1478.

89. **Albugineotomy.**—Senn reports a case of chronic orchitis treated by albugineotomy. He thinks that this method is often better for the relief of tension, drainage and resolution of primary pathologic products than castration, which is too frequently resorted to. Albugineotomy should be tried and will be found successful in the majority of cases if the entire organ is not too seriously involved. In acute orchitis in the absence of suppuration, incision should not be performed. In performing future operations of this nature he would modify the technic by scarifying the parietal tunica vaginalis and attaching this surface to the testicle by several catgut sutures through the cut margins of the tunica albuginea, thus facilitating a firmer and more rapid organic union between the two structures.

90.—See abstract in THE JOURNAL, xxxix, p. 1478.

91. **X-Ray Work.**—Pennington describes his apparatus, especially the shields for the tube.

92. **Genito-Urinary Tuberculosis and Gonorrhea.**—Eisendrath offers the following conclusions from his study of the cases here reported and the literature:

1. That in patients suffering from an acute gonorrhea, there may be an almost imperceptible transition into a malignant type of tuberculosis.
2. That subacute or chronic gonorrhea may mask the presence of a tuberculosis. That these, as well as the acute form, may act as predisposing, and even at times as exciting, causes of tuberculosis.
3. In patients who show evidence of local complications of gonorrhea, such as prostatitis, vesiculitis, cystitis or epididymis, one should always bear in mind the possibility of tuberculosis, and examine the urine for tubercle bacilli, if antigonorrheal treatment causes no improvement.
4. In patients with marked tubercular history, an attack of gonorrhea should be carefully watched, and the prognosis be guarded.
5. Gonorrhea, both in the male and female, often prepares the soil for a later invasion of the tubercle bacillus.

97 *A Study of the Distribution of the Colon Bacillus of Escherich and of the Sewage Streptococci of Houston in Polluted and Unpolluted Waters. C. E. A. Winslow and M. P. Hunnewell.

97. **Colon Bacillus.**—From their studies of the subject, including a review of the previous publications, and description of the method of analysis in examination of 157 samples of apparently unpolluted water and 50 samples of obviously polluted water, Winslow and Hunnewell conclude that the use of large samples in applying the colon test is not of advantage in a sanitary analysis of drinking water. The proportion of lactose fermenting organisms and of colon bacilli is increased in the unpolluted waters by the method, and waters of good quality are likely to be condemned, while in polluted water the comparative proportion of bacilli ordinarily present are less during incubation of large samples, and they appear to actually better advantage by the use of 100 c.c. with preliminary incubation in phenol broth. In polluted waters, it is evident that even the incubation of a single centimeter for twenty-four hours in dextrose broth may lead to the suppression of colon bacilli. The idea suggests itself that in the routine sanitary examination the use of dextrose tube alone, with simple determination of the gas formula, or the direct plating of the water in litmus-lactose-agar, without preliminary incubation, might give more useful practical results in some cases than the usual procedure. It is desirable that more comparative work should be done on these tests. It is unsafe to assume that red colonies on the litmus-lactose-agar plate indicates the presence of organisms of the colon group. Subcultures should be made whenever it is desired to form any idea as to what groups are represented. Comparison of the results of analysis of 1 c.c. samples shows a striking difference in the distribution of the sugar-fermenting organisms in general. It seems that bacteria capable of growing at the body temperature and fermenting dextrose and lactose are only infrequently present in unpolluted waters. They also show that by the method employed, *Bacillus coli* is very rarely found in 1 c.c. samples of unpolluted waters. This confirms the observations of Smith and the English bacteriologists as to the parallelism between the numbers of colon bacilli present in a water and the extent of its contamination. When *Bacillus coli*, as defined by the tests noted, is found in such abundance as to be isolated in a large proportion of cases from 1 c.c. of water, it is reasonable proof of the presence of serious pollution. The group of streptococci and staphylococci seems to be associated with sewage pollution when present in any number. While the principal object of the analysis was to find *Bacillus coli*, it seems probable that these two groups of sewage organisms normally occur together, and that when this is the case gas will be

formed by the *Bacillus coli* in the first fermentation tube. When both colon bacilli and streptococci are present, the latter apparently overgrow the former during the preliminary incubation. The presence of either one, then, becomes significant. It is desirable that the occurrence of the streptococcus, as well as the colon bacillus, should be noted in sanitary water analysis. With these two apparently characteristic sewage forms, and with perhaps also the *Bacillus sporogenes*, the bacteriologist finds himself in a better position to draw reliable conclusions as to the antecedents of a water sample than has ever before been the case.

102 *The Curse of Gonorrhea. Joseph T. Johnson.
103 *Parotitis Following Abdominal Section. W. H. Morley.

98. **Ureterovesical Anastomosis.**—Hunner reports two cases and describes in detail his method of operating. He first severs the ureter at the desired point and controls hemorrhage. The renal end of the severed ureter which is to be inserted is split along its anterior and posterior walls for a distance of one centimeter, thus forming two lateral flaps. An incision two or three centimeters long is made in the fundus of the bladder, which may be called the "working incision." After choosing a point where the ureter will enter the bladder wall, usually high up, and as laterally as possible, a small incision is made by inserting a scalpel through the working incision and pushing it through the bladder wall from within. Two mosquito forceps are then passed through the working incision and out through the anastomosis opening, each grasping one of the lateral flaps of the ureter. Next comes the first two of the four sutures for the anastomosis; these are mattress sutures preferably of black silk, which pass through the serous and muscle coats only, and serve to draw the ureter into the bladder and to fasten its anterior and posterior walls to the anastomosis opening in the bladder wall. The more difficult posterior suture is first passed. It enters the bladder wall from the rear, and after penetrating the serosa and muscularis leaves the wall very close to the anastomosis opening; it then takes a similar hold on the posterior ureteral wall, about one-half centimeter above the level of the split, and crossing above the split, it grasps the posterior wall again and descends to enter the bladder wall on the other side of the anastomosis opening, entering this time from an anterior direction and passing posteriorly. A similar suture is set for the anterior ureteral wall. After denuding the flaps of their serous coats, the forceps draw them into the bladder, and the two external sutures are tied. Care must be exercised in passing the suture twice through either the anterior or posterior ureteral wall not to get the two strands too widely separated so as to constrict the lumen when they are tied. They make a very firm anastomosis, but the addition of a square suture fastening each lateral flap to the bladder wall is a simple procedure and gives to the operation its claim to perfect safety. The flaps, still held by the forceps, are everted into the working incision and a rectangular piece of the bladder mucosa, corresponding to the size of each lateral flap, is cut from either side of the anastomosis opening. The flap sutures penetrate all the coats of the flap except the removed serosa and all coats of the bladder except the excised mucosa. They should be passed near the end of the flap to interfere as little as possible with the bladder circulation about the anastomosis. They may be either silk or catgut. If of silk, they must be tied inside, and the cut ends left about two centimeters long, and then through the cystoscope the loops may be cut and removed later. Unless suprapubic cystostomy is indicated the working incision is now closed. Some variations in individual cases may be required and dealt with according to indications. He reports two cases and discusses the various methods. The article is illustrated, which makes the description more clear.

99. **Electrothermic Hysterectomy for Cancer.**—Downes describes the electrothermic angiotribe by which he has performed 5 hysterectomies for cancer; 3 are here reported for the first time. He has also assisted other physicians in similar operations. He describes his instruments which have already been mentioned elsewhere.

100.—See abstract in THE JOURNAL, xxxix, p. 1411.

101. **Conservative Operations on the Ovaries.**—Dunning questions the advisability of always leaving portions of the ovary as a routine practice. The danger of sepsis is considerable. He reports cases and offers the following conclusions:

1. Operations on the ovaries that preserve the menstrual and reproductive functions should be employed in lieu of complete extirpation, especially in cases of extirpation of one ovary, and where the remaining ovary shows, as pathological changes, a single cyst of moderate size, or several small cysts, or a single small hematoma. 2. Healthy displaced ovaries may, with advantage, be anchored in as nearly a normal position as possible by stitching them with fine catgut to the posterior surface of the broad ligament, or by shortening the infundibulo pelvic ligament. 3. Cases of sterile married women and married women who are using means to avoid pregnancy are unfavorable subjects on whom to do conservative operations on the ovaries. 4. The writer believes that in pus cases, such conservative operations should, as a rule, be avoided.

102.—See abstract in THE JOURNAL, xxxix, p. 1339.

103. **Parotitis After Abdominal Sections.**—From the study of a case described in this article and other cases elsewhere reported, Morley concludes:

1. There is an intimate relation between the parotid gland and the abdominal and pelvic viscera. 2. This close relation probably exists through the medium of the sympathetic nervous system. 3. Suppuration or non-suppuration of the parotid gland in these cases depends entirely on the local conditions in the gland. 4. This complication may follow any surgical operation on the viscera of the abdomen and pelvis, but it occurs more often after an ovariotomy. 5. The patient's life is not jeopardized *per se* by the occurrence of this complication. 6. The appearance of the parotid bubo usually marks a turning point in the disease.

2. **Giantism.**—Meige protests against the proposal to foster marriages between giants. He points out that the excessive osteogenetic function is frequently accompanied by more or less general disturbances, showing that it has a tendency to be pathologic. When the excessive osteogenetic function affects the shafts of the long bones, the result is a giant, but when merely the ends of the bones are involved acromegaly is the result. Giants are, therefore, of the infantile or acromegalic type, according as osseous union between the shaft and the epiphysis occurs early or late.

14 Ibid. Keiler.
15 Zur Casuistik des Abortus provocatus. B. S. de Smitt.

7. **Leucocytosis During Pregnancy.**—Hahl found in 36 patients that the number of white corpuscles was somewhat increased during the last days of pregnancy. Marked hyperleucocytosis was observed with the onset of labor, chiefly due to an increase in the proportion of the polynuclear neutrophile cells. During the puerperium this hyperleucocytosis gradually subsided and normal conditions were re-established by the end of the first week.

10. **Origin of Amniotic Fluid.**—Silberstein's article won the university prize at Berlin for 1901. It is a study of a case of twins, one oligohydramnic and the other polyhydramnic, and suggests that the difference in the amount of fluid observed was due to the fact that one fetus urinated more profusely than the other. In pathologic cases such as these Nature allows us a peep behind the scenes, he remarks, and what we see establishes Gusserow's theory that the amniotic fluid is essentially a product of the fetal organism and of the kidneys in particular.

19. **Effects of Experimental Castration.**—Lüthje castrated two male and two female dogs and kept control pairs out of the same litters. As the animals grew up it was impossible to detect any difference in metabolism between the castrated and the uncastrated animals during the three years that elapsed before they were killed. There is evidently a substitution of function by other organs in respect to metabolism and no specific influence can be attributed to the generative glands. No difference was apparent between the animals in regard to either the composition of the blood, amount of hemoglobin or iron, nor in the behavior, shape, growth or disposition.

20. **Relations Between Functional Renal Disturbances and Albuminuria.**—Cloetta found on administering aloin, cantharidin or potassium chromate to rabbits that while these various poisons caused different functional disturbances in the kidneys yet the microscopic picture was almost identical in each. In the experiments with aloin, the disappearance of the albumin was not necessarily followed by resumption of normal renal function. Lines representing the freezing-point and the albuminuria ran parallel at first and then in some cases abruptly intersected each other. This indicated that notwithstanding apparent improvement of the kidney lesion the organ was incapable of resuming its function. Such a condition may

explain certain cases of sudden death in acute nephritis when the patient is apparently improving. The experiences confirm the assumption that the noxious influences responsible for the production of acute nephritis may affect the renal function in widely diverse ways. If we can learn the rules governing the differences in this respect we may be able to discover the inner secrets of the pathologic renal function, beyond the reach of pathologic anatomy.

50. Artificial Fertilization of Eggs of Starfish.—Loeb refers to his success in inducing by means of certain ions the development of normal, viable embryos out of unfertilized eggs, but adds that all attempts to induce it by means of enzymes have hitherto failed. The research on the eggs of the starfish, described in the present communication, confirms his previous assumption that the fertilizing action of the spermatozoon depends on its bringing substances into or causing conditions in the egg which accelerate the course of certain, possibly synthetic, processes in the egg. This accelerating influence might likewise be induced by certain ions, and he has proved that this possibility can be artificially realized. He has established in regard to the ova of the starfish that the mature but unfertilized specimens rapidly die in sea water, while the immature and the mature fertilized ova continue to live. This occurs in both natural and sterilized sea water. The ova do not ripen until ejected from the ovary, as oxygen and free hydroxyl ions are apparently necessary for their ripening. When the ripening is artificially hindered by lack of oxygen or by acid environment, the unripe ova retain their vitality much longer than the ripe, unfertilized ones. Fertilization by a spermatozoon or by chemical or physical intervention, prolongs the life of the ovum. The process of ripening, on the other hand, entails the death of the ovum unless it becomes fertilized. Treatment with dilute acid which induces parthogenesis of the mature ovum, checks the ripening process in immature specimens. He thinks that these facts of the ripening of the egg, its natural death and the prolongation of the life of the unripe egg, throw a certain light on the mechanism of the phenomenon of fertilization.

61. Connection Between Viscosity of Sputum and Coughing.—Neumann found in examining nine children with whooping cough that the coughing spasms were always associated with lesser viscosity of the sputum. As the phlegm became thicker the spasms did not recur. He suggests the possibility that the greater fluidity of the sputum and its consequent movability and expansion may be the cause of the coughing paroxysm.

80. **Open-Air Treatment of Tuberculosis.**—Volland believes that much harm is being done by the exaggeration of the importance of fresh air in the treatment of tuberculosis. The patients fail to realize the benefits they should from the sanatorium, as they are constantly allowed to get chilled night and day by the undue importance attached to the benefits of out-of-door air. They are not aware that their vitality is being depressed by the cold air, as they are under the influence of suggestion. Hammer's discovery that the results obtained in his city dispensary actually surpassed those obtained in the sanatoriums should open the eyes of the profession. No one was more astonished than Hammer himself. His patients were too poor to give up the day to lying out of doors, and lived so crowded that the families would have objected if one member had insisted on sleeping with open windows at night. Consequently they did not get chilled to the same extent as the sanatorium patients, and the system was able to cope more effectively with the tubercle bacilli. (Hammer's communication was reviewed in THE JOURNAL, xxxix, p. 284, title 108.)

81. **Bovine Tuberculosis in Prophylaxis of Human Tuberculosis.**—Fuld suggests that the bacillus of "Perlsucht" may yet play an important part in the prophylaxis of human tuberculosis. It seems credible that a system naturally immune to "Perlsucht" might be immunized by means of a bovine tuberculin until it proved refractory to genuine tuberculosis.

86. **Surgery in Typhoid Perforation.**—Miclescu states that about every fourth case of peritonitis due to typhoid perforation and operated on has been cured. Reviewing 226 communications that have been published, he finds that 37 were saved out of 131, that is, about 28.3 per cent. The intestinal lesion is generally single, and surgical intervention should be applied in every case of typhoid perforation. In even the most hopeless cases this treatment postponed the fatal termination.

90. **The MSS. of the Abbess Hildegard.**—This work dates from the twelfth century and is a manual for the etiology and treatment of the ills that flesh was heir to in those days, with suggestions in regard to hygiene, etc. Her remarks show much common sense and intelligent observation.

91. **Treatment of Kidney Stones.**—Klemperer accepts as indications for operation total anuria for twenty-four hours and the onset of acute pyemia. A few cases are on record in which the stone was spontaneously evacuated after forty-eight hours, or even as late as twenty-eight days, but we are not justified in counting on these rare exceptions. He thinks that much injury has resulted from the assumption that renal lithiasis is the expression of a family and hereditary diathesis. It will be found that in nearly every case the abnormal constituents of the urine responsible for the lithiasis can be eliminated from the diet and thus the cause be removed.

92. **Treatment of Pneumothorax.**—Zuelzer describes a case in which the most distressing symptoms were relieved by puncture, but normal conditions could be restored only by repeatedly aspirating with a Bülau siphon drain; the maneuvers continued for several hours.

98. **Study of Freezing-Point of Urine in Bilateral Kidney Affections.**—Strauss has been studying at Senator's clinic for two and one-half years the variations in the freezing-point in various diseases. The tests disclosed great variations in the results even in the same person at different times. They also revealed a certain, but by no means constant, connection between the findings and certain anatomic affections of the kidneys. The quantitative and qualitative behavior of the renal functions under identical conditions of time and of test ingestion of water and of salt, was the aim of the latest research, to discover new points to serve in the diagnosis of anatomic alterations in the kidneys. The subjects had unsalted milk soup for supper the night before, and urinated at 10 p. m. and at 5 and 6 a. m. The next day they ingested 500 c.c. of water, fasting. The second day 10 gm. of cooking salt were added to the same amount of water and taken fasting, and the third day 50 gm. gluton were added to the same amount of pure water. The subjects remained in bed until 11 a. m. and ate nothing until then. The food during the three days of the tests was the same for each subject, and with as little salt as possible. The water test proved most instructive, and he recommends it for general adoption as a valuable aid in diagnosing, although the findings are of course no criterion for the functioning of the kidney at all times, and the test may exceptionally give normal results even in case of severe anatomic alterations. But still, it is a step in the right direction. Strauss establishes the normal freezing-point as 0.91 to 2.43 C. The extremes of range allowed by other investigators have been 0.87 to 2.71. The product of the freezing-point multiplied by the amount of urine in the twenty-four hours, is the most important finding of all, as it indicates the work of the blood-cleansing function of the kidney. This figure is called "V." He found the normal range to be 1,112 to 3,359; the extremes of other investigators have been 766 to 3,770. The percentage of sodium chlorid he found to be normally 0.26 to 2.58; the highest range of other writers has been 0.09 to 2.11. By dividing the freezing-point by the percentage of sodium chlorid he obtained as the normal range 1.01 to 3.54, while others have found it range from 0.98 to 1.69 or 1.83 or 2.33 or even 13.17. Comparing the results of his 150 tests on 16 subjects he noted that a marked and protracted reduction of the functional capacity occurred but rarely, and only associated with edema and with deficient "freezing-point reaction." Extreme oligochloruria usually accompanied the diminished functional capacity and also a pathologically high value for the figure representing the freezing-point divided by the percentage of sodium chlorid. At the same time the elimination of the achlorids was not reduced as a rule. Oligochloruria with its consequences occurred likewise when the organism was unable to eliminate much chlorin on account of inadequate intake or when the elimination in other ways was increased or the sodium chlorid was retained elsewhere in the body in dropsical effusions. We must distinguish, he adds, between a hematogenic or histogenic and the nephrogenic oligochloruria, the same as we distinguish between a hematogenic and nephrogenic oliguria and polyuria. Prolonged oliguria in the absence of anatomic renal affections and edema and not preceded by fasting, is generally normal. The kidneys work atypically, but they work sufficiently. This was observed in several cases of chronic interstitial nephritis. The impression was derived from this research that polyuria is a compensatory re-enforcement of the blood-cleansing function. The edema in such cases fre-

quently varies in strict correspondence with the behavior of "V." There seems to be a tendency in chronic nephritis to maintain the osmotic tension in the urine at the same point on different days.

106. **Curettement of Uterus During Puerperium.**—Wormser tabulates 20 cases and reviews the literature on the subject of curetting the uterus during the puerperium. The results establish that the measure is not indicated in case of retention of membranes nor febris sub partu, nor as a therapeutic measure in case of fever. But it is required in case of hemorrhage, both the severe hemorrhages which follow in the first few days after delivery, and the protracted bleeding in the latter part of the puerperium, rebellious to ordinary measures. The curette must be wide and brutal force avoided. Under these conditions he deems the procedure not only radical and certain but also free from danger.

107. **Rupture of Gall Bladder into the Free Abdominal Cavity.**—A number of cases of subcutaneous rupture of the gall bladder have been operated on according to the literature, including the personal case described by Arx in this article. The symptoms are those of ordinary perforation, with the exception that there are no signs of sepsis. The onset of the collapse is not so sudden as in case of ordinary peritonitis from perforation. In the case personally observed there were no indications of collapse even twenty hours after the perforation was known to have occurred. The temperature was slightly febrile, and there was vomiting, meteorism and pain in the abdomen, in short all the symptoms of paralysis of the intestines, and still the general condition was comparatively good. The tongue was only moderately dry, and there was none of the appearance of distress and depression, the facies Hippocratica, no abrupt variations in temperature, no chills, no enlargement of the spleen. The pulse was strong and did not rise above 110. There was no icterus, no trace of it even in the eyes, and the urine responded normally to the Gmelin test. Between one and two hours after the rupture the gall bladder which had before been palpable, could no longer be distinguished, indicating that the contents had been poured out into the abdominal cavity, while the peritoneum was still free from irritation. The first signs of cholemia appeared the third day in each of the cases. Experimental research has shown that bile thus poured into the abdominal cavity is taken up by the lymphatic vessels and retained by them as a protection to the body, until these vessels become enfeebled and give up the bile to the blood. This occurs in animals in about twenty-four hours, but experience has shown that thirty hours usually elapse before it occurs in man. In the case reported a part of the bile secreted after the trauma found its way into the intestines and was evident in the stools by the fourth day. All the unoperated cases of subcutaneous rupture of the gall bladder terminated fatally sooner or later, while on the other hand, 10 cases treated by puncture alone recovered, and 3 after laparotomy and 5 after laparotomy and removal of gallstones. About 41.1 per cent. of the cases treated by puncture alone terminated fatally, and 20 per cent. of those treated by laparotomy. In Arx's case cystostomy was done, but he regrets that he made a median instead of a lateral incision, as he attributes the lingering of the fistula to the site of the incision. He concludes from his research and experiences that rupture of the gall bladder or biliary passages from the wearing away of the walls by gallstones is a very rare occurrence and seems to be limited to the female sex. The bile in the abdominal cavity is not in itself dangerous. The danger is from the absorption into the blood of the biliary acids. For this reason the bile should be evacuated so soon as perforation of the biliary passages is diagnosed. A laparotomy is preferable to mere puncture. He urges not to wait for symptoms of collapse but to operate at once, and recommends his practice of cleansing the abdominal cavity from the bile with hot saline solution. The peritoneum will bear the brief application of it at even 131 F.

Books Received.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review, as dictated by their merits, or in the interests of our readers.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Volume IV. December, 1902. Diseases of Digestive Tract and Allied Organs; Liver, Pancreas and Peritoneum—Anesthetics, Fractures, Dislocations, Amputations, Surgery of the Extremities, and Orthopedics—Genito-urinary Diseases—Diseases of the Kidneys—Physiology—Hygiene—Practical Therapeutic Referendum. Cloth. Pp. 422. Price, $1.50. Philadelphia and New York: Lea Brothers & Co. 1902.

A MANUAL OF MATERIA MEDICA AND PHARMACOLOGY, Comprising All Organic and Inorganic Drugs Which Are or Have Been Official United States Pharmacopeia, Together with Important Allied Species and Useful Synthetics, Especially Designed for Students of Pharmacy and Medicine, as well as for Druggists, Pharmacists and Physicians. By David M. R. Culbreth, Ph.G., M.D., Professor of Botany, Materia Medica and Pharmacognosy in the Maryland College of Pharmacy. Third Edition, Enlarged and Thoroughly Revised, with 473 Illustrations. Cloth. Pp. 916. Price, $4.75. Philadelphia and New York: Lea Brothers & Co. 1903.

THE PRACTICAL MEDICINE SERIES OF YEARBOOKS, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued Monthly. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume II. General Surgery. Edited by John B. Murphy, M.D., Professor of Surgery, Northwestern University Medical School. November, 1902. Cloth. Pp. 553. Price, $2.00. Chicago: The Year-Book Publishers.

ANATOMY. A Manual for Students and Practitioners. By William H. Rockwell, Jr., M.D., Formerly Assistant Demonstrator of Anatomy in the College of Physicians and Surgeons, Columbia University, New York. Series Edited by Bern. B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York. Illustrated with 70 Engravings. Cloth. Pp. 620. Price, $2.25. Philadelphia and New York: Lea Brothers & Co.

ATLAS AND EPITOME OF HUMAN HISTOLOGY AND MICROSCOPIC ANATOMY. By Privatdocent Dr. J. Sobotta, of Wurzburg. Edited, with Additions, by G. Carl Huber, M.D., Junior Professor of Anatomy and Histology, and Director of the Histological Laboratory, University of Michigan, Ann Arbor. With 214 Colored Figures on 80 Plates, 68 Text-Illustrations. Cloth. Pp. 248. Price, $4.50 net. Philadelphia and London: W. B. Saunders & Co. 1903.

ATLAS AND EPITOME OF DISEASES OF THE MOUTH, PHARYNX, AND NOSE. By Dr. L. Grunwald, of Munich. From the Second Revised and Enlarged German Edition. Edited, with Additions, by James E. Newcomb, M.D., Instructor in Laryngology, Cornell University Medical School. With 102 Illustrations on 42 Colored Lithographic Plates and 41 Text-cuts. Cloth. Pp. 219. Price, $3.00 net. Philadelphia and London: W. B. Saunders & Co. 1903.

SURGICAL ANATOMY AND OPERATIVE SURGERY. For Students and Practitioners. By John J. McGrath, M.D., Professor of Surgical Anatomy and Operative Surgery at the New York Post-Graduate Medical School. Illustrated with 227 Illustrations, Including Colors and Half-tones. Cloth. Pp. xiv-559. Price, $4.00 net. Philadelphia: F. A. Davis Company. 1902.

BOOK ON THE PHYSICIAN HIMSELF and Things that Concern His Reputation and Success, by D. W. Cathell, M.D. The Twentieth Century Edition, being the Eleventh Edition Revised and Enlarged by the Author and His Son, William T. Cathell, A. M., M.D. Cloth. Pp. 411, Price, $2.50 net. Philadelphia: F. A. Davis Company. 1902.

THERAPEUTICS OF DRY HOT AIR. By Clarence Edward Skinner, M.D., LL.D., New Haven, Conn.: Professor of Thermotherapy in the New York School of Physical Therapeutics. Cloth. Pp. 200. Price, $2.00. New York: A. L. Chatterton & Co.

BIOGRAPHIC CLINICS. The Origin of the Ill-Health of De Quincey, Carlyle, Darwin, Huxley and Browning. By George M. Gould, M.D., Editor of *American Medicine*. Cloth. Pp. 223. Price, $1.00. Philadelphia: P. Blakiston's Son & Co. 1903.

TRANSACTIONS OF THE TWENTY-FOURTH ANNUAL MEETING OF THE AMERICAN LARYNGOLOGICAL ASSOCIATION, Held at Boston, Mass., May 26, 27 and 28, 1902. Cloth. Pp. 259. New York: Rooney & Otten Printing Co. 1902.

SEVENTEENTH BIENNIAL REPORT OF THE TRUSTEES, SUPERINTENDENT AND TREASURER OF THE ILLINOIS NORTHERN HOSPITAL FOR THE INSANE AT ELGIN, July 1, 1902. Paper. Pp. 83. Springfield, Ill.: Phillips Bros. 1902.

REPORT OF THE COMMISSION APPOINTED TO CONSIDER THE QUESTION OF A STATE SANATORIUM FOR CONSUMPTIVES. Paper. Pp. 74. Concord, N. H.: The Rumford Press. 1902.

The Public Service.

Army Changes.

Movements of Officers of the Medical Department, U. S. Army, under orders from the Adjutant-General's Office, Washington, D. C., from Dec. 27, 1902, to Jan. 3, 1903:

Cattermole, Charles A., captain and asst.-surgeon, U. S. V., now at San Francisco, will proceed to his home, where he is authorized to await his honorable discharge from the service of the United States, Feb. 1, 1903.

Corbusier, William H., major and surgeon, U. S. A., on the expiration of his present leave of absence, will proceed to Fort Crook, Neb., and report to the commanding officer of that post for duty, to relieve Captain Paul F. Straub, asst.-surgeon, U. S. A., who, on being thus relieved, will proceed to San Francisco, and report to the commanding general, Department of California, for duty to accompany troops to the Philippine Islands.

De Shon, George D., major and surgeon, U. S. V. (captain and asst.-surgeon, U. S. A.), is relieved from further duty in the Division of the Philippines, and will proceed to San Francisco, and on arrival report by telegraph to the Adjutant-General of the Army for orders.

Lyster, William J. L., first lieut. and asst.-surgeon, U. S. A., is ordered to proceed to Ft. Wayne, Mich., for duty.

Russell, Frederick F., first lieut. and asst.-surgeon, U. S. A., is granted an extension of leave for fourteen days.

Stone, John H., captain and asst.-surgeon, U. S. A., is detailed as member of the examining board to meet at Ft. Leavenworth, Kan., vice Lieut.-Col. John Van R. Hoff, deputy surgeon-general, hereby relieved.

Thompson, Louis A., contract surgeon, U. S. A., is relieved from duty at Ft. Thomas, Ky., and will proceed to his home, Dayton, Ohio, and on arrival report by letter to the Surgeon-General of the Army for annulment of contract.

Wells, George M., captain and asst.-surgeon, U. S. A., is relieved from further duty at Fort Wadsworth, N. Y., to take effect on the expiration of his present leave of absence, and will then proceed to Ft. Bayard, N. M., and report in person to the commanding officer, U. S. General Hospital at that post, for duty, to relieve First Lieut. Horace D. Bloombergh, asst.-surgeon, U. S. A., who will then proceed to San Francisco, and report in person to the commanding general, Department of California, for assignment to duty with troops en route to the Philippines, and on arrival at Manila, will report in person to the commanding general, Division of the Philippines, for assignment to duty.

Willcox, Charles, major and surgeon, U. S. A., now at San Francisco, will proceed to Ft. Totten, N. Y., and report in person to the commanding officer of that post for duty, and by letter to the commanding general, Department of the East, to relieve Major Edwin F. Gardner, surgeon, U. S. A. Major Gardner, on being relieved, will proceed to Ft. D. A. Russell, Wyo., and report in person to the commanding officer of that post for duty, and by letter to the commanding general, Department of Colorado, to relieve Captain William F. Lewis, asst.-surgeon, U. S. A. Captain Lewis, on being thus relieved and on expiration of the leave of absence heretofore granted him, will comply with the provisions of Paragraph 17, Special Orders, No. 276, Nov. 24, 1902.

Navy Changes.

Changes in the Medical Corps of the Navy for the week ended January 10:

Medical Director E. S. Bogert, retired, detached from the Naval Recruiting Station, New York, and to continue duty at Marine Recruiting Office, New York.

Medical Director T. Wolverton, retired, ordered to the Naval Recruiting Station, New York.

Asst.-Surgeon J. H. Holloway, commissioned assistant-surgeon from Sept. 26, 1902.

P. A. Surgeon J. A. Guthrie, detached from the *Yorktown* and ordered to the *Vicksburg*.

Asst.-Surgeon K. Ohnesorg, detached from the *Vicksburg* and ordered to the *Yorktown*.

Asst.-Surgeon A. E. Peck, detached from the *Annapolis* and ordered to the Naval Station, Cavite, P. I.

Asst.-Surgeon U. R. Webb, detached from the Naval Station, Cavite, P. I., and ordered to the *Annapolis*.

Medical Inspector F. B. Stephenson, retired from active service, on account of disability incurred in the line of duty, Jan. 3, 1903, to continue duty at Naval Hospital, Portsmouth, N. H.

Medical Inspector S. H. Dickson, detached from the *Iowa*, and ordered to the *Newark* as Fleet Surgeon of the South Atlantic Station.

P. A. Surgeon H. H. Haas, detached from the *Montgomery* and ordered to the *Prairie*.

P. A. Surgeon J. E. Page, detached from the *Newark* and ordered to the *Montgomery*.

Marine-Hospital Changes.

Official list of the changes of station and duties of commissioned and non-commissioned officers of the Public Health and Marine-Hospital Service for the seven days ended Jan. 8, 1903:

Surgeon Preston H. Bailhache, granted leave of absence, on account of sickness, for 30 days from January 6.

Surgeon H. R. Carter, leave of absence for three days from Jan. 5, 1903, under Paragraph 179 of the regulations.

P. A. Surgeon J. B. Greene, relieved from duty at New York (Stapleton).

P. A. Surgeon S. B. Grubbs, to proceed to Guaymas, Mexico, for special temporary duty.

Asst.-Surgeons H. B. Parker, R. H. von Ezdorf, and J. F. Anderson, to report to chairman of board of examiners at Washington, D. C., Jan. 12, 1903, to determine their fitness for promotion to the grade of passed assistant-surgeon.

Asst.-Surgeon D. E. Robinson, relieved from duty at Seattle, Wash., and special temporary duty at Port Townsend Quarantine, and assigned to duty at Port Townsend Quarantine.

A. A. Surgeon J. M. Keyes, granted leave of absence for thirty days from January 5.

A. A. Surgeon F. F. Sams, granted leave of absence, on account of sickness, for thirty days from January 1.

Pharmacist F. L. Brown, granted leave of absence for ten days from December 25.

Pharmacist W. F. Schlaar, relieved from duty at Washington, D. C., and directed to proceed to Boston (Chelsea), and report to medical officer in command for duty and assignment to quarters.

RESIGNATION.

A. A. Surgeon J. M. Keyes, resigned, to take effect Feb. 3, 1903.

BOARD CONVENED.

Board convened at Washington, D. C., Jan. 12, 1903, for the examination of assistant-surgeons to determine their fitness for promotion to the grade of passed assistant-surgeon. Detail for the board: Asst. Surgeon-General W. J. Pettus, chairman; Asst. Surgeon-General G. T. Vaughan; Asst. Surgeon-General H. D. Geddings, recorder.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended Jan. 10, 1903:

SMALLPOX—UNITED STATES.

California: Sacramento, Dec. 20-27, 1 case; San Francisco, Dec. 21-28, 12 cases.
Colorado. Denver, Dec. 20-27, 3 cases.
Illinois: Chicago, Dec. 27-Jan. 3, 6 cases.
Indiana: Dec. 27-Jan. 3, Evansville, 1 death; South Bend, 1 case.
Maine: Biddeford, Dec. 27-Jan. 3, 26 cases.
Maryland: Baltimore, Dec. 27-Jan. 3, 1 case.
Massachusetts: Boston, Dec. 27-Jan. 3, 20 cases, 4 deaths; Cambridge, Dec. 27-Jan. 3, 5 cases; Chelsea, Dec. 26-Jan. 2, 1 case; Fall River, Dec. 27-Jan. 3, 3 cases; Lawrence, Dec. 27-Jan. 3, 1 case.
Michigan: Grand Rapids, Dec. 27-Jan. 3, 7 cases.
Nebraska: Omaha, Dec. 27-Jan. 3, 3 cases.
New Hampshire: Dec. 27-Jan. 3, Manchester, 8 cases; Nashua, 2 cases.
New Jersey: Camden, Dec. 27-Jan. 3, 3 cases.
New York: Dec. 27-Jan. 3, Buffalo, 1 case; New York, 4 cases.
North Carolina: Charlotte, Dec. 1-31, 126 cases, 21 deaths.
Ohio: Cincinnati, Dec. 26-Jan. 2, 7 cases, 1 death; Cleveland, Dec. 27-Jan. 3, 7 cases, 1 death; Dayton, Dec. 27-Jan. 3, 10 cases.
Pennsylvania: Dec. 27-Jan. 3, Altoona, 3 deaths; Erie, 5 deaths; Philadelphia, 15 cases, 1 death; Pittsburg, 16 cases, 7 deaths; Williamsport, 1 case.
Rhode Island: Newport, Dec. 27-Jan. 3, 1 case, 1 death; Warwick, Dec. 24-31, 4 cases.
South Carolina: Charleston, Dec. 27-Jan. 3, 4 cases.
Tennessee: Memphis, Dec. 27-Jan 3, 4 cases.
Wisconsin: Green Bay, Dec. 28-Jan. 4, 2 cases; Milwaukee, Dec. 27-Jan. 3, 4 cases.

SMALLPOX—FOREIGN.

Argentina: Buenos Ayres, Oct. 1-31, 12 deaths.
Belgium: Ghent, Nov. 8-15, 1 death; Dec. 6-13, 2 deaths.
Brazil: Bahia, Nov. 29-Dec. 13, 12 cases.
Canada: Quebec, Dec. 20-27, 2 cases.
Ecuador: Guayaquil, Dec. 13-20, 3 deaths.
France: Marseilles, Nov. 1-30, 37 deaths.
Great Britain: Leeds, Dec. 13-20, 11 cases; Liverpool, Dec. 13-20, 56 cases; London, Dec. 6-13, 1 case; Manchester, Dec. 6-13, 3 cases.
Italy: Palermo, Dec. 6-20, 25 cases.
Mexico: City of Mexico, Dec. 14-28, 4 cases, 1 death.
Russia: Moscow, Nov. 29-Dec. 6, 4 cases; St. Petersburg, Dec. 6-13, 16 cases, 3 deaths.
Turkey: Constantinople, Dec. 7-14, 1 death.

YELLOW FEVER.

Colombia: Panama, Dec. 22-29, 4 cases.
Ecuador: Guayaquil, Dec. 13-20, 12 deaths.
Mexico: Dec. 20-27, Tampico, 14 deaths; Vera Cruz, 14 cases, 4 deaths.

CHOLERA—INSULAR.

Philippine Islands: Manila, Nov. 2-15, 184 cases, 124 deaths; Provinces, Nov. 1-15, 252 cases, 170 deaths.

CHOLERA—FOREIGN.

Egypt: Alexandria, Dec. 1-13, 82 cases, 64 deaths.

PLAGUE—UNITED STATES.

California: San Francisco, Dec. 11, 1 case, 1 death.

PLAGUE—FOREIGN.

Mexico: Dec. 31, 1902, Ensenada and Mazatlan, officially reported.

SOME UNAPPRECIATED CAUSES OF ANEMIA IN CHILDHOOD.*

W. C. HOLLOPETER, A.M., M.D.

Professor of Pediatrics, Medico-Chirurgical College; Pediatrist to the Medico-Chirurgical and the Philadelphia Hospitals; Attending Physician to the Methodist Episcopal and the St. Joseph's Hospitals.

PHILADELPHIA.

The time was when the child's physician was called only to the acute troubles of childhood, the chronic sufferer drifted on, handicapped by a host of physical imperfections until an acute disorder would terminate the child's life. In many cases of milder specific diseases the child is left to fight its way back to health, scarcely reaching, unfortunately, its original vigor.

DENTITION.

Primary dentition, a physiologic process, is often a time of ill health and suffering to the child, but when this is complicated by the administration of improper food, irregularly given, which sooner or later disturbs the child's balance, we frequently find the little patient markedly anemic at the end of this period.

For the last few years my attention has been constantly drawn to some of the unrecognized, or at least, unappreciated causes of anemia in growing children. We know the anemias of the acute diseases and specific blood changes; of these I do not wish to speak. I have long felt that the gastrointestinal tube was at fault more than the effect of irritating food, and that these conditions might be avoided if the child possessed a clean mouth and if its personal hygiene was all that we could desire.

DENTAL DECAY.

The great primal cause of anemia in children, and the factor least recognized and yet most prevalent, is dental decay. While the majority of children's physicians are alive to this source of infection, the mass of general practitioners pay but little attention to this important factor, and hence, not until the child becomes markedly anemic and has associated with it, by reason of this lowered resistance many complicating troubles, do they awake to a realization of its importance. Dental decay furnishes more cases of anemia, is more prevalent, is least appreciated of all the disorders of childhood. In a child from 6 to 10 years of age it is a very common thing to find teeth in an advanced state of decay, with a condition of pus formation and general septic involvement of the whole alimentary canal. Too little attention is paid to saving the first teeth. If careful attention is not given to them a general hyperemia of the oral cavity occurs, with numerous alveolar abscesses, which empty their pus contents into the stomach. Bad teeth prevent thorough mastication, and in this way contribute materially to a deranged gastrointestinal tract. A general catarrhal inflammation is created that renders the child irritable, provoking a severe trial to his disposition, if not changing his temperament, and thus laying a foundation for anemia which will require years of correct living to outgrow. I have watched a great many children at this age, during the period of second dentition, and have found their mouths, with few exceptions, in a septic condition. This pathologic condition could not exist in any other portion of the body without comment or immediate correction. It goes on, however, in about 90 per cent. of all children, at this age, uncorrected, unnoticed.

In children with weak digestion and irritable dispositions we are constantly correcting their habits or administering moral suasion instead of removing the pus generating, foul, decaying teeth. The surgeon will wash his hands and sterilize his patient before an operation on the mouth, jaws or stomach, yet at the same time the mouth of this patient will possess numerous pus-producing fountains. An interesting question to be settled by the physician in the future is to what degree the broken health or perverted disposition of children can be traced to decaying teeth with their contributing pus streams to the system.

It has long been a serious question whether gastrointestinal catarrh could ever be removed. If a septic oral cavity continues for several years we feel quite sure the individual can scarcely regain his usual vigor. A child thus loses the high standard he is entitled to because this essential of his growth is ignored. Nothnagel[1] calls attention to the following trite truth regarding catarrhal inflammation: First, a real cure of an acute catarrh can only be brought about through the regenerating processes going on in the organism or the affected tissues. Second, complete recovery is only possible in acute catarrh. The second point is especially emphasized and the assertion is made that a chronic intestinal catarrh is incurable. It is therefore of the utmost importance to prevent the acute catarrh from becoming chronic. This can be accomplished not so much by medication as by careful regulation of diet and régime and careful toilet of the teeth. With carious teeth in early childhood we will have imperfect digestion, and with defective digestion we will soon have gastrointestinal catarrh and its accompanying anemia. Second dentition is fraught with tremendous import-

1. Praktitscheski Vratch, vol. I, No. 7.

ance; the rapid development of the whole body, especially the unstable nervous system, makes it a season of great watchfulness and not least among the many clashing elements to engage our attention are the teeth, rapidly undergoing decay and being replaced by new ones. Neglect of a proper toilet of the teeth will bring us stomatitis of every degree of intensity: ulceration sloughings, gangrene, pyorrhea alveolaris. In the jaws, by extension, we will frequently find periostitis, alveolar abscesses, necrosis; and in the soft parts in the neighborhood of the mouth, by continuity of structure, we find by reason of the septic condition of the mouth, recurrent tonsillitis, pharyngitis, otitis, glandular inflammation, cellulitis, and possibly meningitis by direct extension. The coroner of Philadelphia, a medical man, some years ago informed me in a conversation that fully 50 per cent. of the cases of death in young children falling under his observation were due to oral sepsis. This contribution to the anemias of childhood by reason of decaying teeth is, in my mind, preventable. Dr. William Hunter, in his admirable essay on oral sepsis, makes this startling yet unappreciated statement, that dental caries is the commonest and most prevalent infection in the body, and that this infection is of a mixed character, including not only the harmless organisms, but also the most active pathogenic blood poisoning organisms, namely, the streptococci and staphylococci.

NASAL STENOSIS AND MOUTH BREATHING.

The second unrecognized factor in contributing to the anemia of childhood is breathing through the mouth, due to nasal stenosis. Stenosis of the nose is a most frequent inheritance of the infectious diseases. Whooping cough, measles and influenza contribute a large percentage of such cases, the catarrhal inflammation having fastened itself on the mucous membrane of the nasal chambers during the process of the disorder, the hypertrophied turbinated tissue serving to block the channel. The careful toilet of the nose during the acute catarrh will serve to bring this tissue under control. The constitutional effect of mouth breathing is familiar to us all. The flattened chest, vacant look, open mouth, dull intellect, due to deficiency of oxygen to the system, must bring on anemia. This condition is quickly recognized by the specialist, but the children's physician should also early inform his patient so as to prevent it by careful and early training.

EYE STRAIN.

Another frequently unrecognized factor in producing anemia in growing children is eye strain. A child's school life is one of artificiality. They read in school with "political" print, poor light and defective ventilation; this has brought many children to wearing glasses. Some years ago in making a comparative study of letter press used in school books throughout the world, it was discovered that the German text afforded 10 per cent. more defective eyesight in the young than the English print. If correction of this eye strain could be quickly brought about we would save a long train of suffering for the young child; but for years the child is treated for catarrh of the stomach, headache and nausea and a long train of discomforts due to car riding or crowd sickness, while the unstable condition of the eye muscles is really at fault. Finally, the eyes are corrected and this long train of symptoms vanishes, not, however, until the nervous system has long been unbalanced, shocked by headache, and a train of toxemias, generated by the unstable system, has poisoned the blood and anemia is the result.

CONCLUSIONS.

From this brief outline I can conclude that the mouth in children is most frequently unhygienic, giving rise to gastrointestinal troubles; remote infectious diseases are common, including all troubles due to pyogenic organisms, as osteomyelitis, ulcerative endocarditis, empyema, suppurative meningitis, suppurative nephritis, not to exclude the more obscure septic conditions characterized by irregular fever, purpura, bleeding gums and various toxic conditions. Again, we must recognize the fact that there must be a limit to the power of the stomach to cope with a constant stream of pus pouring into it from the decaying teeth. The acid of the gastric juice may destroy the toxic influence for a time, but it is eventually overwhelmed and ill health the result. Again, asepsis of the mouth of the child (adult also) is as much to the physician as is asepsis to the surgeon—a necessity to life and health.

DISCUSSION.

DR. I. A. ABT, Chicago—This paper brings home to us very forcibly the need for the proper care of the teeth. However, so far as the causation of anemia is concerned, we must consider the subject in a broader sense. Secondary anemias are to be regarded as symptoms of a variety of diseases. While it is true that diseases of the upper intestinal tract may produce blood changes, still we must look for the cause of the anemias in some change in nutrition or metabolism or some more serious disorder in the disposition of the food or in some grave toxemia, which, perhaps, has its seat in the intestinal tract. By absorption through the lymph channels toxins may produce profound changes in the blood. When one calls dentition, decaying teeth and eye-strain causes of anemia there are undoubtedly some of us who dissent from such views.

DR. JOHN LOVETT MORSE, Boston—There is no doubt, of course, that dental caries and eye-strain may be causes of anemia in children. The author of the paper has, however, made a number of statements which I think it would be very difficult for him to prove. He says dental caries is the most common cause of anemia in childhood. How can he tell in a given child whether it is the decay of the teeth, inherited weakness of constitution or the environment, for example, which causes the anemia? How can he tell whether indigestion is secondary to decayed teeth, decayed teeth to indigestion, or both to improper food? I fear his argument is "*post hoc, propter hoc.*" Dr. Hollopeter tells us, moreover, that 90 per cent. of all children have dental caries, and yet I think that even he would not claim that 90 per cent. of all children have anemia. I think the pathologic changes do not, as a rule, go on in children to a chronic gastrointestinal catarrh; the condition is rather a disturbance of digestion, not a distinct catarrh. Again, I do not see how eye-strain can really "poison the blood"! If so, the process must be a very indirect one.

DR. J. C. COOPER, Philadelphia—I appreciate what the author has said regarding the fact that decay of the teeth frequently produces anemia. The child is naturally more rapid in chewing, and the toxic conditions may be contributing causes. I recall a case of a boy who had been suffering for some time with poor teeth, and who for some time previous to my seeing him had been in an anemic state. He had also contracted the tobacco habit, and although not quite 9 years of age he had begun to chew tobacco, in order, as he said, to relieve his toothache. This tobacco habit, with the gastrointestinal catarrh, made it impossible to cure him. He died of some meningeal inflammation of a peculiar type associated with malassimilation. It seemed to me that many anemic conditions could be explained by some form of nerve strain or nerve tax. I have seen a great deal of anemia in children who have been allowed or encouraged to take part in public addresses and public entertainments. Just what effect public speaking has on the nerve centers and digestive function is uncertain, but it certainly makes the child peevish and interferes with

its proper nourishment. Such a child becomes anemic. It is rather difficult to say how well a child can dispose of purulent conditions in the mouth. Experience would indicate that strong children can take care of a good deal of this. In my experience anemia has been usually associated with some perversion of the nervous system of the child together with improper food which should have been corrected early.

DR. A. C. COTTON, Chicago—Though appreciating the positions taken by Drs. Abt and Morse, I think we all agree with Dr. Hollopeter in some of his conclusions, and with the remark of the last speaker that anemia in children is not infrequently the result of poor hygiene. I believe it can be demonstrated that improved hygiene in such children will result in an improved condition of the blood. All will admit that a child suffering from dental caries is in a condition of poor hygiene, for perfect digestion of food can hardly go on under these circumstances. Again, adenoids or mouth breathing, by causing shallow respiration and insufficient oxygenation of the blood, undoubtedly lead to anemia. We have all seen cases in which after operations for increasing the capacity of the upper respiratory tract an improved state of the blood has resulted. We can not measure the infection from the gastrointestinal tract, but clinically we must respect the possibility of the decomposition of the gastrointestinal contents, with consequent intoxication. No one will contend, I think, that infection is compatible with good blood conditions, so that although all of the steps from the premise to the conclusion have not been established by Dr. Hollopeter, I believe all the statements made in the paper are demonstrable clinically.

DR. MORSE—I think my remarks were somewhat misunderstood. I do not deny that dental caries, interference with the air supply and even eye-strain may indirectly cause anemia; what I did dispute was the statement that dental caries is the most common cause of anemia in childhood.

DR. C. G. KERLEY, New York—My work for the past fourteen years has brought me a great deal among the out-patient poor in New York City, and among them I have met with a great many cases of anemia. In the majority of cases it has seemed that the anemia was dependent on improper feeding in the second year of life. We hear very little, indeed, about how the baby should be fed in this period, and this is usually left to the family or nurse. These children are often fed to a great extent on crackers and bread, and the milk is not of good quality. If we paid more attention to the feeding of run-about children, and saw that they were fed sufficiently on proteids and not too much on starches there would be much less anemia.

DR. J. P. CROZER GRIFFITH, Philadelphia—The speaker has not mentioned the fact, of course known to him, that rachitis, although extremely common in childhood, is constantly overlooked, and is an important cause of anemia. Since it also predisposes to the early decay of the teeth, it is possible that both the dental caries and the anemia are the result of the same cause, rather than that the former produces the latter.

DR. HOLLOPETER—I did not try to cover the whole ground in my short paper, and hence I endeavored to merely call attention to a generally neglected part of our work, i. e., the toilet of the child's mouth. The highest percentage of oral sepsis comes from England; if I remember correctly it was so stated by Dr. Hunter.

Carbolic Poisoning by Vaginal Douche.—At the Orleans Parish Medical Society meeting, Nov. 22, 1902, Dr. Fenner described a peculiar case of carbolic acid poisoning in hospital. The patient was being given a 2 per cent. carbolic solution as a vaginal douche, and while the nurse's back was turned, removed the nozzle, but on being admonished replaced it (as the nurse thought) in the vagina. Suddenly she collapsed and sank into unconsciousness, the pupils became contracted, the pulse thready and the patient had a number of convulsions. The interne being summoned and recognizing the probability of absorption per rectum dilated the sphincter ani. Thereon there was a gush of the carbolic solution, showing that the patient had placed the nozzle in the rectum instead of the vagina. Irrigations of magnesium sulphate were given and atropin in large doses administered hypodermatically. The patient recovered.

RETROPHARYNGEAL ABSCESS IN INFANCY.*

JOHN LOVETT MORSE, A.M., M.D.
Instructor in Diseases of Children, Harvard Medical School; Assistant Visiting Physician at the City Hospital and at the Infants' Hospital.
BOSTON.

Retropharyngeal abscesses are usually divided into two classes: primary, or idiopathic, and secondary. The secondary class is made up of those due to disease of the vertebræ and of those due to the direct extension of abscesses from neighboring parts. The primary form is infinitely the more common in infancy and is the only one to be considered here. The greatest number of cases occur between four months and one year; 83 per cent. of Bókay's cases were under two years and 75 per cent. of Holt's under one year.

ANATOMY.

The retropharyngeal lymph nodes form a chain on both sides of the median line of the pharynx extending from its upper portion to its junction with the esophagus. They lie between the prevertebral aponeurosis and the muscles of the pharynx. In infancy they drain the cavities of the cranium, pharynx, nose and middle ear. They are said to atrophy after the third year and in some instances to disappear entirely.

MORBID ANATOMY.

Enlargement of these lymph nodes is called retropharyngeal adenitis; suppuration, retropharyngeal abscess. This form of retropharyngeal abscess is that which is known as primary or idiopathic. Both retropharyngeal adenitis and abscess are very seldom truly primary, however, but are almost always secondary to inflammation of some of the cavities drained by these nodes. In some cases infection seems to follow inflammation of the mouth. The pathology is the same as that of adenitis and suppuration of the external cervical lymph nodes. Several nodes are usually involved in simple adenitis, but suppuration rarely takes places in more than one. Suppurative inflammation is accompanied by a cellulitis of the surrounding tissues. Very few bacteriologic examinations of these abscesses have been made. It is probable that any of the pus-forming organisms may cause them. Koplik, however, found streptococci in all his cases. Bókay has reported a case due to the tubercle bacillus.

Retropharyngeal abscess is, as already stated, always preceded by retropharyngeal adenitis. The symptoms of retropharyngeal adenitis are in no way characteristic, being very similar to those of nasopharyngeal catarrh. Fever is generally slight at first, but usually rises with the progress of the disease. Inspection shows nothing definite in the throat, but the enlarged nodes are easily felt by the finger. It is probable that resolution of these nodes, as of similarly inflamed nodes elsewhere, frequently takes place. There is little or no data on this point, however. Suppuration, when it occurs, usually develops in from five to six days. Originating as it does from a single gland situated to one side of the median line, the abscess is in the lateral wall rather than in the back of the pharynx.

SYMPTOMS.

The symptoms of retropharyngeal abscess are usually preceded by those of retropharyngeal adenitis, which, as already stated, are much the same as those of nasopharyngeal catarrh. With the advent of suppuration the

---

temperature usually rises and becomes more irregular. The first symptom directly due to the abscess which is usually noted is unwillingness to take food or difficulty in swallowing. In the beginning this is probably due to pain, later to the mechanical obstruction of the tumor. Modification of the voice and difficulty in respiration next develop. These vary according to the location of the tumor. If the abscess is in the upper portion of the pharynx the cry is nasal and nasal respiration is chiefly disturbed. The mouth is kept open and the breathing is snoring and snuffling. If the abscess is low down the cry is laryngeal and the respiration is stridulous, like that in laryngeal spasm or stenosis. In these cases the respiratory murmur is diminished locally and many moist râles are heard. These may be due to a complicating bronchitis, but are usually the result of the interference with respiration. In the acute cases the head is held in a most characteristic position from the first, the neck being extended and the head turned to one side. In the subacute cases this may not appear for some time. Swelling of the lymph nodes at the angle of the jaw on the affected side soon develops and may become very marked. The following case is a very typical one:

Case 1.—Francis L. was nursed for five months. As his mother developed erysipelas he was taken off the breast and put on condensed milk. This caused a slight diarrhea and occasional vomiting. He also developed a "cold in his head." About a week after he was weaned he began to swallow with difficulty. A day or two later it was noticed that he kept his mouth constantly open and could not breathe through his nose. He was seen a week later. He was then taking almost no food and was unable to breathe at all with his mouth closed. He had lost much weight and strength. Both inspection and palpation showed a bulging of the left side of the pharynx, most marked in the upper portion, almost filling the throat. Incision let out about two drams of pus and afforded almost instant relief.

DIAGNOSIS.

Although the symptoms of retropharyngeal abscess are usually so characteristic they are very frequently misinterpreted. If the obstruction is high up they are most often mistaken for those of a simple pharyngitis or rhinitis. Sometimes diphtheritic paralysis is suspected. If the obstruction is low down they are often ascribed to laryngitis, catarrhal or diphtheritic. In a number of cases which I have seen, one of which is reported later, the signs in the lungs have caused the condition in the throat to be entirely overlooked and have led to the diagnosis of bronchitis or bronchopneumonia.

The chief reason that a retropharyngeal abscess is so often overlooked is that it is not thought of, and hence is not even considered in the differential diagnosis. Another reason is that inspection of the throat is trusted and palpation omitted. Inspection; however, is often insufficient and may lead to grave errors in diagnosis. In the majority of cases the tumor is visible, but not infrequently, especially if low down, it can not be made out. It can always be felt if present, although if it is situated low down the finger must be introduced very deeply. In no case in which the symptoms in any way suggest a retropharyngeal abscess should palpation of the throat be omitted. It causes the infant only temporary discomfort and may prevent very serious mistakes in diagnosis. The swelling is usually situated in the side of the pharynx, but may be at any level. It is either tense and elastic or fluctuating. If the condition is simply an adenitis the lymph nodes are felt as hard masses, round or oval in shape, and varying in size from that of a pea to that of a large bean. The examination of the throat is best made with a tongue depressor and not with a gag, as Snow had a case in a boy of 15 months in which death immediately followed the introduction of a gag. Holt had a similar case of asphyxia on the introduction of the gag, but his case recovered. The death and asphyxia were probably due to some disturbance of the vagus, as the abscess was not ruptured in either case.

In some rare instances a sudden attack of dyspnea may be the first symptom to call attention to the local condition. In others a small abscess may develop so insidiously as to cause neither general nor local symptoms. The following case is an example:

Case 2.—Charles P. was born Oct. 31, 1899. There was no history of syphilis in the parents and there had been no miscarriages. He was well for the first six weeks except that he had a purulent nasal discharge. He then had a discharge from the right ear lasting four days. About that time he began to have convulsions which continued up to the time of his entrance to the Infants' Hospital, Jan. 5, 1900, when nine weeks old. He had always had more or less disturbance of the digestion and had never gained properly.

He was small and flabby. His head was microcephalic. He had snuffles and kept his mouth open. He swallowed without difficulty. The ears showed nothing abnormal. The physical examination was otherwise negative.

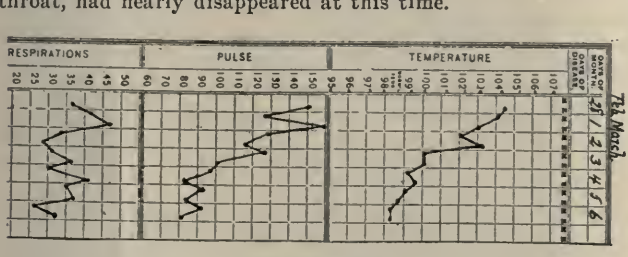
He had no more convulsions and developed no new symptoms. The temperature was normal, and there was no increase in the rate of the pulse or respiration. On January 10, in the course of a routine examination preparatory to showing him at a clinic, a marked bulging was found on the right side of the pharynx. The abscess was opened on that day by Dr. Augustus Thorndike and a small amount of pus let out. A second opening was necessary on January 13. The throat was normal on January 16.

PROGNOSIS.

The prognosis depends largely on the treatment. In untreated cases the usual termination is death. Death may occur slowly as the result of progressive weakness or asphyxia, but more often suddenly from laryngeal spasm or some disturbance of the function of the pneumogastric nerve. The abscess seldom opens spontaneously. This happened but 19 times in Bókay's 144 cases. If it opens spontaneously into the pharynx death may result from suffocation or from a consecutive inspiration pneumonia. The pus may burrow in various directions. In some instances the carotid artery has been opened; in others the abscess has opened externally. In a number of cases it has discharged through the middle ear. In a five-months-old baby which I saw with Dr. Augustus Thorndike at the Infants' Hospital, it ruptured into the external auditory canal just external to the tympanum. The prognosis in cases which are properly treated, that is, by incision, is very different, however, the mortality in such cases being only about 5 per cent.

The following case is a fair example of the results of operation:

Case 3.—George T., 13 months old, began to refuse his food February 24. He was feverish and lost weight rapidly. He did not vomit and his dejections were normal. He was brought to the out-patient department of the Infants' Hospital on February 28, where the following note was made: Fairly developed and nourished. Pale. Puffiness of face under right angle of jaw and also of folds of neck. Tonsils large, but not markedly red. No exudate, no membrane. Percussion of lungs normal throughout. No bronchial respiration. Many coarse moist râles throughout both lungs. Looks septic.



The diagnosis of bronchitis was made and he was admitted to my service the same day. The physical examination, made soon after, was, so far as it is important in this connection, as follows: Appearance septic. Puffiness about the eyes. Consider-

able general, soft, non-fluctuant swelling in the right neck from about the angle of the jaw, extending forward over the neck to just beyond the median line and downward over the clavicle. Respiration somewhat difficult. Movement of alæ nasi with respiration. Mouth open. No retraction of suprasternal, supraclavicular or intercostal spaces. Percussion of lungs normal. Respiration of normal character but diminished in intensity. Numerous moist rales throughout both chests, both back and front, many of them being transmitted from the throat. The throat was full of thick mucopurulent material which rendered examination difficult. Inspection showed swelling of the right tonsil and pharynx behind the tonsil. Palpation showed that the right tonsil was pushed forward by a swelling in the pharynx behind it. It extended downward to the level of the larynx.

A knife was introduced into this swelling and somewhat over a dram of pus evacuated. Respiration became easier at once. The neck was poulticed and vigorous stimulation begun.

The general condition was somewhat better on the next day. He still had some difficulty in swallowing, but breathed much better. The swelling in the throat was somewhat less, and not nearly as tense. The external swelling was unchanged.

On March 2 the lungs were clear, the swelling in the neck was much less and the swelling in the throat smaller. The cry was strong and the breathing nearly normal. On March 4 he swallowed without difficulty, and on March 6 sat up in bed of his own accord. The swelling, both of the neck and in the throat, had nearly disappeared at this time.

TREATMENT.

Cold applications to the neck are advised for the treatment of retropharyngeal adenitis. It must be very seldom, however, that this condition is recognized early enough to offer much hope for the success of abortive treatment. It is much more reasonable to endeavor to hasten the almost inevitable suppuration by the use of poultices and hot applications to the throat. Spontaneous evacuation should not be awaited. The abscess should be opened as soon as the evidences of suppuration are present.

Certain authors advise operation through the neck on the ground that an internal incision affords less efficient drainage, is more likely to close up and offers more opportunity for secondary infection. These arguments are undoubtedly correct. Drainage is less efficient in the internal operation, and second or even third incisions are sometimes necessary. The very favorable results of the internal operation show, however, that these objections are not important. Secondary infection is, moreover, extremely unusual. On the other hand, the external operation is a delicate one and requires a skilful surgeon and assistants, while the internal incision can be performed by any physician at any time without skilled assistance. Moreover, the external operation requires dressing and leaves a scar, while the internal calls for nothing but cleansing of the mouth and the occasional expression of the contents of the abscess with the finger.

The incision is best performed with the infant in the upright position. If it is tipped forward the instant the incision is made there is no danger of the pus entering the air passages. The knife should be guarded except at the point. A gag should not be employed because of the danger of sudden death from its use, but the mouth held open with the finger or a tongue depressor. The abscess should be squeezed once or twice a day with the finger in order to keep up drainage and to prevent the opening from closing. Repeated incisions are sometimes necessary. It is also well to wash out the mouth from time to time with some mild antiseptic solution.

DISCUSSION.

DR. I. A. ABT, Chicago—I have been, in times past, impressed with the relative rarity of this disease. It might be said, perhaps, that we do not recognize the condition, but those of us who have spent some time in the larger European cities, and particularly Vienna, know that it is almost of weekly occurrence to see these abscesses at the clinics. In my own city it has been rather rare to see these cases. In the past winter I saw a little baby in the children's ward of the Cook County Hospital suffering from respiratory obstruction. The mouth was open, the child was snuffling and there was more or less fever. It occurred to me that there might be a retropharyngeal abscess, and on introducing my finger I found a mass as large as a hickory nut lying to one side of the median line. I asked the hospital physician to make an incision, which he did on several occasions, but there was no discharge of pus. The case proved one of the non-suppurating variety of retropharyngeal adenitis. The mass disappeared in ten days or two weeks. In several cases that I have operated on a small incision has been made with a guarded knife, the artery forceps being used later to dilate the incision after the first escape of pus.

DR. ROSA ENGELMANN, Chicago—I should like to ask whether simple incision of a tubercular adenitis would cure that condition.

DR. J. LOVETT MORSE, Boston—I personally have never seen a case of primary tubercular retropharyngeal adenitis, and I have found only one case reported in the literature. About a month ago a gentleman in New York reported a case that he had seen. That case had been treated by incision, and had done well.

DR. F. E. FRONCZAK, Buffalo—Three or four months ago I saw a baby of about nine months with an abscess which I was about to open. As I pressed on the abscess preparatory to an incision it suddenly threw its head back and died despite all efforts at artificial respiration. I tried the Laborde and other methods of resuscitation, but in vain. I suppose that pressure on the vagi might have caused the death in this particular instance. I believe that the introduction of the finger and the pressure downward is dangerous on this account. Even if death does not ensue from the pressure on the vagi, there is always danger in holding the baby's head up, in the possibility that the pus may enter the trachea. I believe that the baby should be held head down.

DR. J. L. MORSE, Boston—I believe I mentioned the only two cases on record of sudden death in this class of cases, and in both of these a mouth gag was used. There is, of course, a certain element of danger in opening the mouth in the internal operation, but it does not count for much in comparison with the advantages of this operation.

DR. C. G. KERLEY, New York—In 1890 another case occurred in the New York Infant Asylum at Mount Vernon, N. Y. The case was reported by Dr. H. E. Tuley several years ago. I introduced my finger and made considerable pressure with the intention of opening the abscess, when the child suddenly stopped breathing. I promptly inserted an intubation tube and performed artificial respiration, the child being held head downward. That child recovered, and, so far as I know, is living to-day. I believe that the pressure made by the finger caused the abscess to disect downward, producing sufficient pressure on the larynx to obstruct the breathing. Intubation unquestionably saved the patient's life. I have seen ten or twelve cases of retropharyngeal abscess, one of them being a double abscess. This child came to me at the New York Polyclinic There was retropharyngeal adenitis on one side and an abscess on the other side, which we opened. Five or six days later an abscess formed at the site of the adenitis and was opened.

Dr. J. P. Crozer Griffith, Philadelphia—I wish to call attention to the great ease with which the diagnosis is made in the typical cases, and also to the very great tendency to overlook these cases because they are not thought of. The peculiar position of the head and the sputtering respiration are so characteristic that the attention should at once be directed to the possibility of retropharyngeal abscess being present. I was called a year and a half ago to one of the suburbs of Philadelphia to see a case in the practice of a very busy and able practitioner. He had never before seen an instance of retropharyngeal abscess, and consequently and naturally did not recognize it, although the aspect of the child was perfectly typical. In another instance the abscess was on the point of bursting externally, and yet the attending physician had never thought of examining the pharynx, as the affection appeared to be a submaxillary adenitis. This case was opened externally because it was pointing in this direction. A probe was afterwards easily introduced from the outside to the posterior wall of the pharynx. To neglect operation in cases of retropharyngeal abscess is a most serious mistake. When the operation is done it should be done thoroughly, a free incision being made and the opening being then dilated, so as to secure drainage. A small incision may easily close within twenty-four hours, allowing the symptoms to return. I have seen this filling up happen several times in the same case.

Dr. J. V. Kofron, Cleveland, Ohio—It seems to me hardly possible that pressure on the abscess is the cause of the sudden death in the cases reported. Dr. Kyle has, on several occasions, in my presence, cut the pneumogastric on one side during an operation, and this has not caused death or any severe shock.

Dr. Frank X. Walls, Chicago—It seems to me that children of the lymphatic constitution would be very apt to die in this way, and that perhaps this explains the sudden death in the reported cases. These abscesses would be apt to occur in such children, and the administration of chloroform or the throwing backward of the head is said to predispose to sudden death. In my opinion, the lymphatic constitution would explain the sudden death better than the theory of pressure on the vagus.

Dr. John Lovett Morse, Boston—I do not feel competent to answer this question, for I am rather skeptical as regards the lymphatic constitution. These cases are to me very obscure, and I do not feel satisfied with the lymphatic constitution as an explanation. In order to show how common retropharyngeal abscess is and how often it is overlooked, I may say that I have had three casesc of retropharyngeal abscess admitted to my hospital service in two days, the abscess not having been made out previously in any one of them.

SPONTANEOUS HEMORRHAGES IN NEWBORN CHILDREN.*

ISAAC A. ABT, M.D.
CHICAGO.

Hemorrhages into various tissues and organs and from mucous surfaces are observed in newborn children. Two varieties occur: 1, Traumatic or accidental hemorrhage; 2, spontaneous hemorrhage.

The traumatic or accidental hemorrhages are due to external causes. The pressure exerted on the head during a long sojourn in the narrow birth channel is one of the most frequent causes. The trauma thus incurred may give rise to hemorrhage between the pericranium and the cranial bones, causing cephalohematoma, or the hemorrhage may occur within the cranial cavity into the brain or meninges. The application of forceps is not an infrequent cause of intracranial hemorrhage. Spencer,[1] who had an opportunity to study 130 cases at autopsy, concluded that this was one of the most common causes of this deplorable accident. Nevertheless, the asphyxia which results during the birth of a child and the congenital weakness of the vessel walls must be regarded as predisposing factors in the production of hemorrhage. At times, however, the violence exerted by the use of the forceps, or the pressure on the head by the maternal parts is so great as to result in rupture of vessels of whatever strength.

Spontaneous hemorrhages are not caused by any injury received during the act of birth. The bleeding is apparently spontaneous in origin, and consists of an oozing from the smaller vessels, or of more extensive hemorrhage from the mouth, stomach, the bowel or the umbilicus. The hemorrhage may occur subcutaneously; it may issue from the nose, the ears, the conjunctivæ, the vagina or into any of the internal organs or serous cavities. The bleeding usually occurs from more than one location, though, in the milder cases, there may be but one bleeding point.

During the past few years I have seen a number of cases of spontaneous hemorrhage, either in hospital practice or in consultation. These records are more or less complete, those seen in hospital practice being the more carefully summarized.

Case 1.—Baby Johnson, born Feb. 2, 1900, male; weight, three pounds and four ounces, at birth. The child was immediately placed in the incubator. It was put to the breast at 3 o'clock the following morning, and nursed well. A hemorrhagic spot the size of a twenty-five-cent piece was noted over the spine at birth; small purpuric spots were also noticed, distributed over the entire face. After passing meconium, the child weighed three pounds and two ounces. Its maximum temperature on February 2 was 101.

On the day following its birth, some hemorrhage was noted around the child's navel; its skin seemed shriveled. The spot over the spine had increased to the size of a dollar. It passed a good night. Urine was highly colored and meconium had an offensive odor.

On February 4, the oozing from navel continued. The child's maximum temperature on this day was 101.1. Odor of stools still offensive. The hemorrhagic spot on back had increased to the size of a small saucer and covered the entire back. On this day there was hemorrhage from the nose, mouth and the vomitus contained blood. Child not able to nurse and was much jaundiced. February 5: The child had passed a very restless night and had cried as if in great pain. It was not able to swallow food, and the general oozing still continued. It died on the morning of this day, at 7:40 o'clock.

Autopsy.—The autopsy in this case was made by Dr. Alice Hamilton, professor of pathology at the Northwestern University Woman's Medical School. Her report is as follows:

Child is emaciated, skin jaundiced and wrinkled, abdomen prominent. A large purplish area occupies lumbar region and extends to sacrum; the scalp also shows a purplish discoloration. The umbilical cord is dry and a dry blood clot covers the stump of the cord. The thoracic cavity is empty, the thymus not enlarged, pleuræ normal. The lungs are smooth, crepitant; on the edges of upper right lobe are noted two small hemorrhagic spots, each the size of a bean; small hemorrhagic spots are also seen on the under and lateral surfaces of lower lobe of right lung. Throughout the lungs are distributed numerous tiny ecchymotic spots. The cut surface of the lung shows congestion. The pericardial sac is normal; the heart is apparently normal, the foramen ovale is closed. The abdominal cavity is empty, the liver is smooth, gall bladder empty. Cut surface of the liver shows greenish color; the lobular markings are indistinct. The spleen is hard, dark red in color, rather large; malpighian bodies prominent, capsules not thickened. Kidneys lobulated, yellowish green in color; the capsules slightly thickened, but strip off easily. A section of the adrenals shows congestion or hemorrhage in center; the margins are yellowish-green in color. The stomach is empty, showing small ecchymoses in mucosa. The intestines are partly filled with

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Diseases of Children, and approved for publication by the Executive Committee: Drs. Edwin Rosenthal, H. M. McClanahan and Samuel W. Kelley.

semi-fluid, brownish matter. The large intestine shows ecchymotic spots. The bladder is full of urine and there are small pin-point ecchymoses into mucosa. The spinal canal is full of clotted blood, there are slight hemorrhages into meninges, the brain is very soft, but there are no gross lesions.

Histology.—The histologic examination reveals a parenchymatous inflammation of the kidneys, congestion and slight induration of the spleen, a deposit of newly-formed connective tissue between the lobules of the liver, congestion and hemorrhagic infarction of the lungs. The smallest vessels have been closely examined without detecting any pathologic changes in the vessel walls.

CASE 2.—Baby R., born March 6, 1901. Weight at birth, 2 pounds and 14½ ounces.

The mother of this child was about 17 years of age, unmarried. She had suffered an attack of pneumonia some three weeks prior to birth of child, and was still ill with bronchitis when admitted to hospital. She had made repeated attempts to produce an abortion during pregnancy. Labor was normal.

The child's skin was pale at birth; eyes were clear. A peculiar, circumscribed, white spot with a well-marked red border about the size of a three-cent piece, was noted on the left arm. It appeared as if carbolic acid had been dropped on the arm, thus bleaching the skin; this area was covered with fine scales. Similar spots were observed, one on the foot and two on the head. The thermometer only registered 93 at birth, and the child appeared quite lifeless. It was at once placed in the incubator and stimulants applied.

On the following morning the child's temperature was 98. It was fed a dram of mothers' milk every half hour. A hot bath was given and the child rubbed with oil. Its weight was now 2 pounds 13 ounces. A large quantity of urine was voided and its condition seemed good.

On the third day of its life it nursed from the bottle; it had lost an ounce in weight. On the whole, the infant did not appear quite as well as on the previous day.

On the fourth day the lowest temperature was 96 F.; in the evening it had risen to 101. The child nursed from the mother during the night, but during the day was fed with a spoon. It was noted that the child seemed weak during the morning and had lost three ounces in weight. On this day an oozing was observed from the roof of the mouth. The white spots previously referred to had disappeared.

On the fifth day of its life there was hemorrhage over the lower portion of the spine. The odor of the stools was markedly offensive. There was a good deal of hemorrhage from the mouth and styptics were used to control the same, without avail. The maximum temperature on this day was 99.6. Child did not take its nourishment well.

On the sixth day oozing of bright red blood was observed from the navel, which was the first bleeding from the cord noted in this child. The stools were very dark and contained blood. Gelatin was applied to the umbilicus and also to the mouth. It was fed mothers' milk with a medicine dropper, but did not take nourishment well. At noon the temperature dropped to 96 F. and at 7 p. m. of the same day it rose to 101.4. The umbilical oozing had become a severe hemorrhage and the stools were decidedly bloody. Hemorrhage also occurred from the nose, mouth and around the periphery of the umbilicus. A clot of blood was expelled from the bowel. Purpuric spots on the face were observed, which increased in size. A nitrate of silver solution was applied to the gums and a 2 per cent. solution of gelatin was given hypodermically; a compress of the same was placed over navel and subsequently a compress of sterilized vinegar was applied without effect.

On the eighth day of the baby's life it had lost an ounce in weight. Hemorrhagic spots were diffusely distributed over the skin and clotted blood was passed from the bowel. The child was very anemic, the extremities were cold and it seemed to be failing. A large clot of blood was passed from the nose. The temperature sank to 95.8 at one time, and did not go above normal on this date. One dram of gelatin solution was administered by mouth and fluid extract of ergot in 1 minim doses was given every two hours. The child was freely stimulated and the use of styptics was continued, but it gradually failed and died at 10 o'clock on the following morning.

Autopsy.—The autopsy was made by myself five hours after death. Skin extremely pale. The cord is dry around the periphery and the umbilicus gives evidence of recent hemorrhage. Large hemorrhagic area under the skin, on the posterior aspect of the left thigh and in the right thigh a similar hemorrhagic area, one and one-quarter inches long by one-quarter inch wide. This was the site of the subcutaneous gelatin injection. Over the sacrum a bluish-red hemorrhagic area the size of a dollar is seen; blood is also noted about the anal orifice. There is evidence of recent oozing from the nose. Lying subcutaneously in the loose skin of the neck, opposite the cricoid cartilage, is a clot of blood the size of a hickorynut. There are two hemorrhagic areas in the right lung. On the anterior surface of the lung, lying underneath the visceral pleura, is an irregular-shaped hemorrhagic area about the size of a three-cent piece; it resembles a small infarct. In both right and left lungs, numerous punctate and miliary hemorrhages occur. The lungs are not completely dilated; atelectactic areas are observed here and there. The thymus gland is normal in size and is the site of diffuse hemorrhage. There is no hemorrhage into the pericardium. The thyroid gland is normal in size and presents numerous punctate hemorrhages. Petechial spots are observed on the periosteum of the ribs. The long bones when cut vertically, show the evidence of syphilitic osteochondritis, fairly well marked. The stomach shows numerous minute hemorrhages into the mucosa; these vary from a pinpoint to a pea in size. The stomach was greatly dilated with air, which escaped when incision was made. There is considerable blood contained in the organ. The heart is negative. The intestines show numerous small hemorrhages into the mucosa. The liver is normal in size and color, but there are small hemorrhagic areas distributed over the surface of the organ. A small hemorrhage is observed in the tip of the appendix. The bladder is negative. The suprarenal capsules are the site of slight hemorrhages. The kidneys are pale, but otherwise negative. The spleen is somewhat enlarged and congested, and small hemorrhagic spots are numerous throughout the organ and on the capsule. The bones of the skull are negative, though hemorrhages are observed under the pericranium. The brain substance is pale and there are no large hemorrhagic areas noted in it, but some small petechiæ in the pia mater. There is slight diffuse injection of the pia mater.

Unfortunately, no histologic examination was made in this case. The bacteriologic examination gave us no results.

CASE 3.—The following case was seen in consultation with Dr. A. L. Freund of this city: A female child was born March 24, 1899, after a tedious, though otherwise uneventful labor. It seemed somewhat feeble after birth, though it cried normally and showed no gross lesions. When about thirty-six hours old, the child became intensely jaundiced, and soon thereafter severe hemorrhages occurred from the anus, mouth and vulva. The hemorrhages continued, the child became more and more exhausted and all attempts to control the hemorrhages by internal medication and by external applications, were futile. Death occurred on the fifth day of the child's life.

The etiology in this case is obscure. Dr. Freund suggests that the nurse was careless in the treatment of the cord, and fears that an infection may have resulted in this manner. In the family history lues is denied. The father had a slight pulmonary hemorrhage ten or twelve years before the birth of the child; he is, however, robust and appears to be in good health. The mother is a well-developed woman and appears to be in perfect health. In her childhood she is said to have had a severe bowel disease, which persisted for a long time.

CASE 4.—This case was seen in consultation with Dr. Edward Buel Hutchinson of this city. The child was delivered by Dr. Hutchinson, June 30, 1901. It weighed 8 pounds and 1 ounce. The position was l.o.p. The labor was prolonged and forceps were used because there was no advance of the head. Some difficulty was experienced in the labor and considerable maternal hemorrhage ensued. The membranes were incomplete. The fetal heart tones were 140 per minute and were strong. There was slight asphyxia at birth.

The father of this child is 42 years old, a hard drinker, but appears robust and claims to be in good health. He absolutely

denies syphilitic infection. The mother is 36 years of age, a primipara and in good health.

On the third day of the baby's life, the respirations were rapid, the temperature varied from 103 to 104, cyanosis was marked and the urine stained the napkins a pinkish hue. On the fourth day it nursed very little and did not seem as well.

July 4, the fifth day, the temperature continued high, purpuric spots were noted on the neck and chin and a few drops of blood exuded from the vagina. On the sixth day a purpuric eruption was seen distributed over the chest, trunk and extremities. It nursed poorly and bleeding was observed from the gums, vagina and rectum. On this day I was asked to see the child. Its respirations were rapid, it was intensely pale and exhausted, the heart's action was rapid and there was some cyanosis. The child did poorly from this time on; it lost steadily in weight, the bleeding continued from all the mucous membranes unabated, the hemorrhages into the skin increased in size and number. Convulsions occurred, followed by coma, and the child died on the eleventh day of its life.

Various local and constitutional remedies were employed in this case—subcutaneous injections of normal salt solution, suprarenal extract locally and internally, inhalations of oxygen. No autopsy was permitted.

CASE 5.—Baby B., born prematurely (7½ months), was brought to the hospital a few hours after birth and placed at once in an incubator. On its arrival its temperature was 102 and it weighed 4 pounds 5 ounces.

The mother of this child had been anemic for years. She had married five years before and this was her first child; at its birth she was about 24 years old. No specific history can be obtained from either father or mother.

The baby's maximum temperature on the second day of its life was 104.2. On the third day it was noticed that a small, greenish, offensive stool had been passed. The child was given small doses of calomel. The maximum temperature on this day was 103.4. The baby was bathed and was fed mother's milk with a teaspoon in dram doses every two hours. On the fourth day the stools continued very offensive. The child had lost nine ounces in weight since its birth. The temperature continued elevated on the fifth day; the child nursed from its mother.

On the sixth day, for the first time, hemorrhagic spots were observed on the face and on the body, varying in size from a millet seed to a pea.

The temperature was somewhat lower on the seventh day, and on the eighth day a hemorrhagic spot was observed over the lower portion of the spine. The bowel movements were offensive and temperature rose to 102. On the ninth day, it was stated that the loss in weight continued. It rested well during the night. The child was taken from its mother's breast and nursed by a wet-nurse.

On the tenth day a slight gain in weight was noticed, the child's condition seemed somewhat improved, and the hemorrhagic spots were less marked. I saw the child on this day, for the first time. Examination showed a greatly enlarged spleen, which was hard and reached almost to the anterior superior spine of the ilium. The liver was also enlarged.

On the thirteenth day of the child's life it was not nursing well, its temperature became subnormal during the night, though it slept well and cried little. It lost slightly in weight, the urine was highly colored, oozing was observed from the mouth, and the face assumed a cyanotic hue. Its general condition was not so favorable on this day.

On the fourteenth day the spots were much more marked and the child's skin and mucous membranes remained cyanosed. Purpuric spots were noted over the spine; there were several of these, which gradually coalesced to form a hemorrhagic area.

On the fifteenth day it had made a slight gain in weight; it passed a great quantity of urine and for a number of days the urine had been very scant. It was given citrate of potash every two hours. The child continued to do fairly well, the hemorrhagic spots gradually became paler, it took mothers' milk from the breast and left the hospital weighing 3 pounds 13¼ ounces. After reaching home it continued to improve, made a steady though slow gain in weight. It was placed on antispecific treatment, consisting of daily inunctions, which were continued for two or three months. When the child was about 4 months old, it was noted that a slight nystagmus was present in both eyes and that the head was gradually increasing in size. The child passed from under observation for six weeks; upon its return to the city, it was noted that a decided hydrocephalus had occurred. The spleen continued large.

The child is alive at the present day, the hydrocephalic condition shows a tendency to diminish.

CASE 6.—Baby H., born Sept. 12, 1901, female child. Labor normal. The maternal history is negative, though her first baby died from a hemorrhage from the navel. There is a slight suspicion of a luetic infection in the father, though this is not fully confirmed. The baby's weight at birth was 6 pounds and 8 ounces. The cord was tied in the usual manner at birth and it was soon noticed that a hemorrhage was occurring at this point. The cord was retied by the attending obstetrician. After he left the hospital, it was observed that the bleeding had not ceased and a third ligature was applied. The oozing still continued around the periphery of the cord and a firm compress dipped in a 2 per cent. gelatin solution was now applied to the navel. The temperature was not elevated on the day of the child's birth. On the following day a slight hemorrhage occurred from the nose, and the child vomited blood; its temperature fell to 96 F. Quarter-grain doses of chlorid of calcium three times daily were ordered, and 1 per cent. solution of gelatin was given three times a day in dram doses. The mother was given calcium chlorid.

On the third day of the baby's life the temperature was 96.4 and did not rise above normal all day. The crying was weak; the stools contained traces of blood. On this day a fresh hemorrhage started from the cord and a compress soaked in sterile gelatin was applied, after which the child was placed in an incubator.

On the fourth day it seemed to go into collapse; the skin was cyanotic, there was no more hemorrhage from the navel, the heart's action was very rapid and respiration was of a decidedly Cheyne-Stokes character. The child had muscular twitchings and convulsive seizures, there was dulness over the left lung posteriorly, with tubular breathing above and diminished breathing at the base. Fear was expressed that the baby would survive but a few hours. A slight quantity of blood was vomited.

On the fifth day the child was nursing, the hemorrhages had ceased and it appeared decidedly better. From this time on the baby improved; it slept well; the cord fell off on the ninth day without affecting the excellent condition of the child. Mercurial inunctions were employed. The baby left the hospital in good condition; it is now two months old and is progressing favorably.

CASE 7.—The following case was reported to me verbally by my friend Dr. Julius Hess, who had an opportunity to observe it fully while he was at the clinic of Escherich in Graz. The case was worked up by Dr. Kovalevsky, a Russian woman who was studying at the clinic.

The child was brought to the hospital on the third day of its life and placed in an incubator. It had been prematurely born and was poorly nourished. It was fed at the breast of a wet-nurse. Suppuration was noted at the insertion of the cord. About the end of the first week two small cutaneous hemorrhages were observed. These gradually increased in size and underwent discoloration. On the subsequent days of the child's life other ecchymoses appeared.

Examination.—At the time of the baby's death, the skin was of a deep yellow color, its continuity broken only by the stains of more recent hemorrhages. Blood examination showed a great increase of the white blood corpuscles; normoblasts and poikilocytes were present. Several specimens of blood were stained. In one, a whole colony of short, thick bacilli were observed, and in a second specimen a few scattering organisms of the same type were found. Cultures were made on blood serum, agar, gelatin and bouillon from the blood, and showed a pure culture of the same type of organism.

Autopsy.—The dura and meningeal vessels were the site of slight abscesses, most marked on the convexity. Some serosanguineous fluid was found in the pleural and cardiac cavi-

ties. The liver and kidneys were also the site of miliary abscesses and fatty changes. The spleen was enlarged and congested and the navel was the site of suppurative processes.

Bacteriology.—Cultures from the spleen, kidneys, liver and dura mater showed pure growths of the organism referred to above. Gelatin was not liquefied by this micro-organism. The indol test was negative. A mouse injected with one cubic centimeter of a twelve-hour bouillon culture died the next day. The organisms destained by Gram, and were agglutinated by serum from the child before its death. The organism, in accordance with the biologic and morphologic examinations, appeared to be a variety of the colon bacillus, notwithstanding the fact that the indol test was negative. The probable explanation of this rests on the fact that the colon bacillus produced abscesses, which we know it is capable of doing, and the absorption from the pus foci caused the hemorrhages secondarily.

CASE 8.—The following is from Dr. Lobdell's obstetric service at Cook County Hospital, Dec. 26, 1899:

The mother was a primipara, 19 years of age. She was unmarried and showed undoubted evidence of syphilitic infection. She admitted having contracted syphilis during pregnancy. The labor was protracted and difficult, lasting forty hours. The child weighed 3½ pounds at birth and it lived one hour.

Autopsy.—No caput succedaneum present. There is a quantity of clear red fluid in the peritoneal cavity, with masses of fibrous clots floating in it, and many small, subperitoneal clots are observed. The pleural cavities contain bloody fluid. Petechiæ are noticed under parietal pleura. There is a small amount of straw-colored fluid in the pericardial cavity. Petechiæ are seen in parietal layer of pericardium. Numerous hemorrhagic spots are observed under visceral pleura; on section, it is noted that the hemorrhage extends into lung tissue. Blood and frothy fluid exude from cut surface of the lungs. Foramen ovale and ductus arteriosus are patent. The spleen is markedly enlarged; three accessory spleens are present. A whitish patch is noted on capsule, which does not extend into structure of spleen. The kidneys are negative. There is an effusion of blood underneath the scalp. Petechiæ underneath pia mater. There is a large blood clot into falx cerebri and hemispheres of each side. A blood clot of considerable size is observed in the posterior fossa of the right side.

CASE 9.—The following case was observed in my service in the Children's Ward of the Michael Reese Hospital, Chicago:

The child was admitted to the hospital, April 13, 1901. It was somewhat older than those previously described, but it illustrates the septic nature of a proportion of these cases in such a striking manner that it is included in this report. The child was four and a half weeks old. The family history is negative. The mother reported that during the four weeks prior to its admission to the hospital it had been suffering from gastrointestinal symptoms; it vomited occasionally, had some diarrhea and cough. Three days before admission, the child was taken ill and went into a severe convulsion. It began to bleed from the nose and mouth. This condition persisted. On the day preceding its admission, the bowel movements contained dark, clotted and some fresh blood.

Examination.—A discharge of bright red blood from the anterior nares was observed. The pharynx was negative. The lips were pale, the mucous membranes were everywhere anemic. There was a discharge of blood from the right auditory meatus. An examination of the mouth showed small hemorrhages into the mucous membranes of the hard and soft palate. The heart and lungs were negative. The respirations were increased. The spleen and liver examinations were negative. A discharge of blood from the anus was observed; no purpuric areas were seen and there was no glandular enlargement. The following observations are recorded on the history-sheet the day after the child was admitted to the hospital: "Hemorrhage from the right ear and the anterior nares persists. The feces are stained bright red, though at times they contain dark, clotted blood. At other times the entire stool is of a dark red color. The intense anemia continues. The respirations are 84 per minute. The blood examination shows 41 per cent. hemoglobin, 19,200 white corpuscles, 1,975,000 red. Of the white corpuscles, 60 per cent. are large and small mononuclear leucocytes and 40 per cent. are of the polynuclear variety. The maximum temperature on this day was 102.6; pulse was 128."

On the third day after admission a noteworthy and, in many respects, remarkable change occurred. The temperature fell from 104 degrees at 9 o'clock a. m., to 99.4 at 12 p. m. The extensive hemorrhage ceased and the child seemed much improved. A discharge of pus from the right auditory meatus was observed at this time. The child was examined by Dr. George Morganthau, the aurist to the hospital, who reported a flow of blood from the right middle ear, a perforated eardrum and a discharge of fetid pus. Subsequently, a purulent discharge from the left ear occurred.

From this time on the child continued to improve, the mucous membranes assumed a more normal color and the hemorrhagic condition disappeared. Treatment of the ears was continued, under Dr. Morganthau's supervision, the child remaining in the hospital for this purpose, and was discharged May 5, having fully recovered.

CASE 10.—Louis M., aged 8 weeks, was admitted to my service at the Michael Reese Hospital, Feb. 7, 1901. Like the case previously described, it illustrates a class which is undoubtedly of septic origin, though it is somewhat older than the children that are usually described as suffering from spontaneous hemorrhage. The family history is negative. This is the only child.

The Illness.—Four weeks prior to admission, the child's mother noticed that it was restless and cried a great deal. She also observed an enlargement of the scrotum, which, according to her description, seems to have been caused by hydrocele. She consulted a physician who plunged a trocar into the sac, resulting in the withdrawal of several drams of colorless fluid. Since then, the scrotum had been enlarged, tender and swollen. The baby had been fed at the breast and had thrived.

Examination.—The temperature of the child on admission was 98.2; pulse, 152; respirations, 36. Examination showed spots on the right side of the face the size of barley grains. There was a continuous oozing of blood from the nares and from the mouth. The glands were not enlarged, the liver and spleen were palpable, the left testicle was swollen. In the right testicle the epididymis was large, could be easily palpated, but was not painful. The patient presented a subicteric and an anemic appearance. Auscultation of the lungs gave crackling râles, and roughened breathing was heard over both sides.

February 20, ecchymotic spots were observed on the hard palate. On the gums of the upper jaw, fissured areas were observed. These points were bleeding continuously. The tongue was also covered with small ecchymotic spots. The stools contained blood and the child vomited blood. Bleeding continued without interruption. The temperature, which on admission had been scarcely above normal, soon became high and irregular and the child gradually failed. The pulse and respirations were rapid and the child died February 21, having been in the hospital two weeks.

CASE 11.—A female infant born at full term of healthy parents, perfectly normal labor, was seen a few hours after birth with hemorrhages from the mouth and nose, numerous hemorrhagic areas under the skin and bleeding from the bowel. These persisted for three days, until the death of the child.

Autopsy.—The autopsy was made five hours after death. Skin, a light lemon yellow, mucous membranes pale. A slight discharge from vulva was noted, which began just after death. Bluish-black discoloration on back. Cord dry; stump appeared moist and was discolored by blood. Postmortem rigidity well marked. Muscular substance extremely pale. Thymus moderate size.

Left Lung.—Pale; posteriorly, subpleural, punctate hemorrhages, and some at the apex. The cut surface showed slight atelectasis, edema and some hemorrhagic areas. Right Lung.—Upper lobe pale; subpleural hemorrhages, lower lobe congested. Heart.—Pericardial sac empty; anemia; valves normal; no clots; very little blood; well-marked hemorrhages under visceral pericardium and over left ventricle. Liver.—Smooth, normal in color and size, glossy, shiny in appearance. Spleen.—Normal size, dark color, cut surface shows spleen soft, dark and brittle. Adrenals.—No hemorrhage.

Right Kidney.—Capsule strips with difficulty; slight hemorrhagic marks under capsule; cortical substance well marked. Pelvis slightly infected; no hemorrhages. Left Kidney.—Hemorrhagic spots in pelvis of kidney; cortex contains fine striæ, vascular markings; pelvis otherwise negative. Stomach.—Mucosa covered with dark, blood-stained mucus. Intestines.—Small intestines filled with blood, which is clearly adherent to mucosa. Mucosa blood-stained. Large intestine filled with blood.

Microscopic Findings.—(April 10, 1902.)—Kidney: Normal, except for small hemorrhage; no bacteria. Spleen: Pulp infiltrated with blood; malpighian corpuscles normal and free from bacteria. Small number of bacteria in pulp. Lung: Marked hemorrhagic area; small patches atelectatic; bacteria in blood vessels—none in tissue.

Bacteriologic Findings.—Cultures taken from heart, spleen, lung and liver at autopsy show pure cultures of *Bacillus coli communis*. No growth from umbilical vein. The colonies on both agar and gelatin corresponded to the typical colon bacillus. Indol reaction was very marked. Gas produced in glucose media; litmus milk acidified. The bacillus in all respects responded to the typical *Bacillus coli communis*.

These microscopic and bacteriologic examinations were made by Dr. Jean M. Cooke.

CASE 12.—Baby F. Age, 5½ months. Was delivered after an apparently normal labor, nursed shortly after birth, and was well until one month of age. The bowels were always constipated. When the child was 4½ months old, the mother noticed that it became restless and shortly after this it was observed that the child held its head a little to the left side. A week later swelling developed in the right side of the neck, which was undoubtedly an enlarged gland; this disappeared a short time before the final illness. Nine days before admission to the hospital (March 7, 1902), the child bled from the nose and began to vomit blood, and epistaxis occurred. This continued. Subcutaneous hemorrhages occurred at the same time. There is no history of hemorrhagic disease in the family and the heredity is otherwise negative.

The baby was sent to the hospital in order that the gelatin treatment and subcutaneous saline infusions might be tried. It had a temperature of 101.6 F. on admission, which rapidly rose to 103. Bleeding from the nose, mouth and throat continued, as did the vomiting of blood and the passage of blood by the bowels.

Shortly after admission, the child was given an infusion under the skin between the shoulders, of one and a quarter ounces of well sterilized, 2 per cent. gelatin solution. It was also given stimulants, saline infusion, one-quarter grain doses of suprarenal extract and a few drops of the adrenalin solution in the nose and mouth, in order to control the hemorrhage locally. Small doses of gelatin were given by the mouth. On the following day another subcutaneous infusion of gelatin was made. The child died on this day.

CASE 13.—The notes of this case were kindly furnished me by Dr. J. C. Hoag of Chicago, in whose service at St. Luke's Hospital the patient was treated. A female child, born at the hospital at full term, weighing 7 pounds and 10 ounces. On the third day the weight was 6 pounds and 14 ounces. On the fifth day it was observed that the temperature registered 101.4, the child did not nurse well, there were eight bowel movements with much blood intermixed. On this day the child was given 100 cubic centimeters of a 2 per cent. solution of gelatin subcutaneously. Some of the same solution was injected into the rectum. The child was extremely pale and feeble. On the following day bloody bowel movements continued. The subcutaneous injection of gelatin was repeated. The temperature ranged between 101 and 102. The seventh day a dram of gelatin solution was given by mouth thrice daily. No blood appeared in the stools and none appeared subsequently. Temperature varied between 103 and 105. On the eighth and ninth days the child showed great improvement, with a temperature varying between 99.5 and 100.5. On the tenth day the temperature again rose to 102 and it was observed that induration was present at the points where the two hypodermic injections had been made. On the twelfth day these areas fluctuated and were incised and drained.

From this time on the patient improved, no further bleeding occurred, the patient left the hospital weak and pallid, but improving. The child weighed 7 pounds and 1 ounce on the day it was discharged.

THEORIES AS TO ETIOLOGY.

Various hypotheses have been suggested as to the causal factors in spontaneous hemorrhage. Landau,[2] whose writings on melena are extensively quoted in the literature, is of the opinion that ulcers are produced in the stomach as the result of a somewhat indirect embolic process. The disease, he says, is frequently observed in weakly children who show signs of cyanosis at birth; in consequence of the delayed respiration and the weak heart action clots are formed in the umbilical vein, or in the ductus arteriosus. From one of these clots, Landau maintains that an embolus is broken off and passes through the right heart, the ductus arteriosus into the aorta, and, finally, lodges in an arterial branch which goes to the stomach, thus causing an area of infarction which very soon breaks down and ulcerates. Such a process has been observed by no other clinician than Landau, and the theory is no longer tenable.

Henoch,[3] in commenting on the theory of Landau, remarks that while ulcerations of the gastric mucosa are quite common in newborn children, melena occurs very infrequently; furthermore, that in those cases where multiple ulcers were found on autopsy, no hematemesis or bloody stools were observed. Exceptionally, he says, an ulceration may explain melena. In the majority of cases the condition is a constitutional one and the explanation of embolism is not satisfactory.

More recently, in 1892, Von Preuschen[4] and Pomorski[5] concludes that injuries to the head which result in the production of cerebral hemorrhages, especially in those cases in which the cerebral peduncles and the fourth ventricle are involved, act as causal factors in the production of spontaneous hemorrhages. These authors maintain that cerebral hemorrhages occurring in the locations described, interfere with the normal mechanism of the vasomotor center. These experimenters produced hemorrhages in rabbits by puncturing the cerebral peduncles and the third and fourth ventricles.

This explanation can not be considered as a satisfactory one in the majority of cases. Numerous autopsies have shown that multiple hemorrhages into the viscera, under the skin and from mucous membranes have occurred without any cerebral hemorrhage; on the other hand, numerous hemorrhages occur into the brain without the production of hemorrhage in other locations.

It has for a long time been maintained that congenital syphilis is responsible for a certain proportion of the cases of spontaneous hemorrhages. Behrend[6] believed that such children are usually prematurely born and die shortly after birth, or, at the most, live only a few weeks. The hemorrhages which he observed were multiple in character. He described a case where the child recovered from hemorrhage, but died later of hydrocephalus. Fischel,[7] who reviewed the work of Behrend, and examined very carefully a striking case, paying particular attention to the microscopic examination of the small vessels, could not agree with him as to the syphilitic origin of the condition. Mracek,[8] who examined nineteen cases of hemorrhagic syphilis, found changes in the blood vessels in 14 per cent. The changes consisted of endarteritis of the small and

medium-sized blood vessels in the submucous tissue of the alimentary tract, and this he considered evidence of the presence of syphilis. The most striking changes which Mracek found was in the capillaries.

In the cases which have been reported in this paper, Case 8 shows a history of syphilis in the mother. In Case 2 the osteochondritis and the presence of a pneumonia, together with the fact that the child was prematurely born and poorly developed, speaks in favor of a syphilitic infection. In Case 5 a syphilitic history is strenuously denied by both father and mother. One is, however, tempted to make a highly presumptive diagnosis of lues in this case. These cardinal facts are significant. The child was prematurely born, the spleen was greatly enlarged, there was recovery after antisyphilitic treatment, and a consequent hydrocephalus developed.

INFECTION AS AN ETIOLOGIC FACTOR.

In recent times the tendency has been to study these cases bacteriologically. Numerous observers have described micro-organisms which occurred in the disease. Klebs[9] described a micrococcus which he found in large quantities in nine newborn children, who had died of hemorrhage. These he injected into young rabbits and succeeded in inducing hemorrhage in them. His results were confirmed by Weigert,[10] Eppinger[11] and Brehn.[12] Babes[13] described a case of sepsis arising from the umbilicus. He isolated a micro-organism from the blood which resembled the pneumococcus. Kilham[15] and Marcelis[16] found in two cases a diplococcus which resembled the pneumococcus. Animal inoculation with this organism did not produce hemorrhage. Gaertner[17] isolated a short bacillus resembling in morphologic and cultural characters the typhoid and colon bacilli. J. P. Mapes,[18] quoted by Holt,[19] found in pure culture in the arteries, in the heart's blood and in the spleen, a bacillus which was apparently identical with that described by Gaertner. Baginski[20] reports a case of sepsis in a sixteen-day-old non-syphilitic child with multiple hemorrhages, in which careful bacteriologic examination showed the streptococcus pyogenes in pure culture, taken from various portions of the body. Neumann[21] describes two cases: one, that of a fourteen-day-old presumably syphilitic child. The bacillus pyocyaneus was demonstrated as present in the body juices, and it was found also microscopically in the liver, spleen and blood. In the second case, that of a six-week-old syphlitic baby with diffuse spontaneous hemorrhages, staphylococci and streptococci were present in the heart, blood, spleen and kidneys. Dungern[22] describes a short, plump bacillus, one or two microns in length and one-half as broad, which stained readily with gentian violet and showed the presence of a light capsule. These capsules remained after the micro-organism was grown on culture material, and proved pathogenic for white mice. Autopsy showed ecchymotic spots in lungs and on serous membranes, death having occurred in from forty to fifty hours. The bacillus resembles in morphologic and cultural characteristics the bacillus of Friedländer. It is also recorded that while this child was in the ward three infants died of pneumonia.

In my series of cases bacteriologic findings were not obtained in every case. The two cases in older children presented all the evidences of septic infection, and are of great interest; they verify the opinions of previous writers on this subject, that a certain proportion of spontaneous hemorrhages are due to sepsis. The case which was verbally reported to me from the Escherich clinic, as well as Case 11, are undoubted examples of colon bacillus infection. A study of a number of these cases impresses one at once with the fact that this disease may be caused by a variety of conditions. It becomes apparent, as we proceed in our analysis of the cases, that no one causal factor is responsible for hemorrhagic diathesis in infants as some writers would seem to infer. It is not probable, in my opinion, that any specific micro-organism will ever be discovered as the sole cause of hemorrhagic disease in newborn children. We should rather regard the hemorrhage as a symptom of any one of a number of infections. The explanation of the fact that infants show a readiness to bleed, should be sought in certain peculiarities of the blood-vessel walls, in abnormal states of the blood, or both, and we might infer that the porosity of the vessel walls is increased in these conditions or that the tendency of the blood to clot is diminished. Examinations of the blood have not shown any changes in its chemistry or morphology. Future research in the etiology of this disease should be directed along the line of histologic examination of the minute blood vessels, contemplating also conditions governing the clotting of the blood.

SUMMARY OF CLINICAL MANIFESTATIONS.

The disease is not of frequent occurrence. In the large foreign clinics, as well as in American obstetric hospitals, the frequency varies from one case in 500 to one in 700 births. The family history may be taken into account. In Case 8 there was a positive history of syphilis. In Case 2 the mother admitted having made frequent attempts at abortion and had suffered from a pneumonia late in the pregnancy. In Case 4 the father was a hard drinker, and in Case 3 the father had suffered from a pulmonary hemorrhage several years before the birth of the child. In Case 5 the mother had suffered from a life-long anemia, and in Case 6 the mother had previously given birth to a child that died of hemorrhage. The admission of a luetic infection, of a pneumonia shortly before birth, of frequent attempts to bring about abortion, should all be regarded as significant, though their relation to the condition under consideration would be hard to establish.

In the newborn children two cases showed signs of hemorrhage at birth, one on the second day, one on the fifth day, two on the fourth day and one on the sixth day; the two septic cases included in this paper showed no signs of bleeding until after the fourth week. The sites of hemorrhage were: Umbilicus, 3 times; under skin, 6; from nose, 4; mouth, 7; stomach, 2; vagina, 2; bowel, 5; ear, 1.

In the larger number of the cases of bleeding from the umbilicus, the flow was of a slow oozing character. In one case a profuse flow occurred, which tended to recur at intervals. The hemorrhages under the skin were in some cases small purpuric spots, but in one case a single spot covered the back. The hemorrhages from the nose were of a slight oozing character; those from the mouth were, for the most part, slight. In several cases ecchymotic spots were observed on the soft palate, and in one case there was a decided fissure on the gums of the upper jaw, from which a continuous hemorrhage occurred. It is interesting to note that hemorrhage from the stomach occurred twice, while hemorrhage from the bowel occurred five times. The blood from the stomach was always of a dark red color. From the bowel the blood was usually dark, it was sometimes clotted and in one case bright red blood was discharged. Hemorrhage

from the female genitalia is of frequent occurrence in cases where there is no hemorrhagic diathesis present; the hemorrhage from the vagina in both our cases was profuse. Hemorrhages from the male genitalia were not observed in any of the cases, nor was there a case of hemorrhage from the bladder. The hemorrhage from the ear, observed in the septic case, was associated with hemorrhage from the mouth and nose, and was the manifestation of a septic condition originating in the middle ear.

Temperature in one of our cases continued subnormal throughout the entire illness; this child recovered. In another it continued elevated, rising as high as 104, and this child recovered. The temperature in another varied between 93 at birth and 101.4; on the fourth day it ranged between 96 and 101.4, constituting a very irregular temperature. With one exception, however, all of the children showed exacerbations of fever.

Cyanosis occurred in two of our cases as a late manifestation. All of the children showed a loss of weight. A few of the cases were icteric, and in one the icterus was intense. The icterus in the mild cases was undoubtedly of physiologic type. In one of our septic cases the disease was ushered in by a convulsion. In another, convulsions occurred shortly before death, and in one child that recovered convulsions and muscular twitchings were prominent symptoms.

It is worthy of note that the evacuations from the bowel were very offensive in odor before the hemorrhage was observed; this observation was made in the majority of our cases.

Is the quantity of blood lost sufficient to cause death? From my own experience, I should say that whereas in some cases the loss of blood continued for several days, in the majority of cases it has been inconsiderable and not sufficient in quantity to cause death. We must rather ascribe the cause of death to a general toxemia, whether it be acute, as a sepsis, or chronic, as a luetic infection. The loss of blood in these cases should no more be considered the cause of the lethal result than would the purpuric spots in a morbus maculosus, in a case of cerebrospinal meningitis with purpura, or the expectoration of rusty sputum in the pneumonia of an adult. No case of hemophilia occurred in our series; indeed, all observers are agreed that this disease is extremely rare during the first few days of life—the hemorrhagic disposition does not show itself till the end of the first year of life. The hemophiliac tendency is frequently hereditary, it occurs after slight or severe traumata. Children who suffer spontaneous hemorrhages, such as form the subject of this paper, if they recover, do not show a disposition to recurrent bleeding on recovery.

TREATMENT.

If we have learned anything from our group of cases concerning the treatment of this disease, we may formulate it as follows:

1. Internal remedies, as ergot, tincture of chlorid of iron and extract of suprarenal gland have absolutely no influence on the progress of the disease.

2. The local treatment of the disease by styptics of whatever kind, packing with gauze (as when the hemorrhage occurs from the vagina), and even the local application of suprarenal gland extract, are without permanent influence on the intensity or duration of the hemorrhage.

3. The ineffectual use of gelatin in Case 12 led us to do some experimental work on normal children with gelatin. While it is true that two of our cases recovered (Nos. 6 and 13) after the use of gelatin, this may be due to a mere coincidence, or to the undoubted power which gelatin certainly possesses to coagulate the blood of bleeding surfaces. The method of using the gelatin is as follows:

A pad of sterile gauze, or a compress, may be soaked in a 10 per cent. gelatin in normal salt solution and applied to the bleeding area. A small amount of bichlorid of mercury may be added to this solution. Its preparation must include careful sterilization. A 2 per cent. gelatin in normal salt solution may be given subcutaneously. This should be sterilized repeatedly—that is, for three successive days. The peptone which is ordinarily added to gelatin for culture material should be omitted, as it counteracts the coagulating effect of the gelatin. From 25 to 50 c.c. of this solution may be given subcutaneously to a newborn infant, and may be repeated once daily.

EXPERIMENTAL GELATIN INJECTIONS IN CHILDREN.

The normal children on whom the treatment was tried were as follows:

Normal Case 1.—A little girl of 4 years, feeble-minded, who was taken into the hospital on account of malnutrition. On the 28th day of her stay in the hospital, she was given a subcutaneous infusion of two ounces of 2 per cent. gelatin solution. Very shortly thereafter the temperature rose to 100.2, followed by another rise to 101; the pulse increased gradually from 92 to 140, and the respirations from 24 to 36. The child was extremely restless, greatly prostrated and the extremities were cold. This condition of affairs continued for 24 hours, when the temperature gradually fell to normal and the pulse and respirations likewise.

Normal Case 2.—W. B. A boy, 9 years old, who was receiving treatment at the hospital for equinovarus, was given three ounces of gelatin subcutaneously, at 9 o'clock in the morning. The temperature very soon rose to 101, pulse to 120 and the respirations to 30 per minute. The child was extremely restless and showed symptoms of a sudden toxemia.

Normal Case 3.—Baby B., aged 22 months. Two ounces of gelatin were injected subcutaneously, which caused alarming symptoms of prostration and collapse, with an elevation of temperature and an acceleration of pulse and respirations.

EXPERIMENTS ON RABBITS.

In this experimental work on children the gelatin used was of the best quality, it was sterilized in the most careful manner, and the best proof that it contained no micro-organisms was that in no case did any abscesses result. It was not deemed wise, however, owing to the grave symptoms of toxemia which resulted, to carry on the work any longer with children, and, therefore, a few rabbits were injected.

Experiment 1.—A rabbit weighing five pounds was given an injection of 60 c.c. of gelatin subcutaneously, March 23, 1902. A few drops of blood taken before the injection showed that the clotting time was 48 seconds. Several drops of blood taken on the day following the injection showed that it clotted in 12 seconds; also, that it clotted quickly over the bleeding point and the hemorrhage was not very active. It was noted that shortly after injection the temperature fell very markedly, though it was soon found that the temperature of the rabbits varied with such wide limits that no reliance could be placed upon it. The 60 c.c. of gelatin did not cause the rabbit any great discomfort, notwithstanding that the same dose was given every other day for a week.

Experiment 2.—A second rabbit was given 28 c.c. March 22. On March 23, it was given 30 c.c. of a 5 per cent. solution of gelatin. This last injection caused the rabbit to lie still, apparently sick. On March 25, 60 c.c. of a 5 per cent. solution were given. He became very quiet again, the blood clotted in from 12 to 15 seconds. March 26 this dose was repeated.

After this injection the rabbit did not eat, but lay in a crouching position, breathing rapidly. On puncturing the ear the wound bled slowly and the blood coagulated in 7 seconds. April 2 the same rabbit was given 250 c.c. of a 5 per cent. solution of gelatin. On the following day he refused food, the respirations were rapid and he was very restless. On the 11th the rabbit was given 500 c.c. of a 5 per cent. gelatin solution. The injection was made about 5 p. m., and the rabbit died during the night. The autopsy was made 18 hours after death. The rabbit, during the time of experimentation, had lost greatly in weight, but no demonstrable lesions were apparent.

Experiment 3.—The rabbit used in this experiment was injected with 500 c.c. of a 5 per cent. gelatin solution. After the injection, the rabbit remained quiet and died three hours afterward.

CONCLUSIONS.

The following conclusions are undoubtedly justified:

1. Subcutaneous injections of sterilized gelatin solution are capable of producing toxic symptoms in children.

2. Large doses of a 5 per cent. solution of gelatin caused the death of rabbits.

The explanation of the toxemia produced by the gelatin is not very far to seek, when one recalls that the gelatin is manufactured from the bones of animals. The decomposition which takes place in these bones gives rise to cadaveric poisons. The resulting gelatin is a complex chemical substance, the exact nature of which is unknown to experts. While it is undoubtedly allied to proteid substances, nevertheless it is not distinctly proteid. Its nutritive value and the changes which it undergoes during digestion have not been determined chemically. The nature of the toxic substances that produced the elevation of temperature, the general condition of prostration and collapse in our patients, we should regard as ptomains. That these ptomains are contained in the gelatin may be inferred from the method of manufacture which has already been alluded to. It is a well-known fact that ptomains may be contained in solutions which are subjected to high degrees of heat, the latter not altering their chemical nature nor their toxic properties. The gelatin of commerce is usually acid in reaction, and this acidity is said to be due to bleaching agents employed, either sulphurous acid or chlorin. The acidity of the gelatin seemed to exert no influence, for in the gelatin neutralized by the addition of alkali, reactions occurred in the same manner.

From these considerations the matter may be briefly stated:

1. Sterilized gelatin injected subcutaneously contains toxic products.

2. These products are probably ptomains.

3. No further proof is needed that gelatin causes more rapid coagulation of the blood when it is exposed to the air.

4. It would be difficult to state what a safe dose of gelatin should be, given subcutaneously to a newborn infant.

5. The local use of gelatin and the use of gelatin by the mouth are warmly recommended and no objection can be urged against their use.

It is almost needless to say that in cases where syphilis is suspected a vigorous antisyphilitic treatment should be instituted in accordance with the methods usually employed for infants.

DISCUSSION.

DR. ROSA ENGELMANN, Chicago—I was glad that Dr. Abt emphasized sepsis as a most probable cause of these conditions. It might be well, if the opportunity arose, to make inoculation experiments to get a better classification and etiologic knowledge on this subject. However, back of the sepsis there is probably a condition which makes these children liable to sepsis. One of these is, of course, syphilis. In the larger number of the cases reported in the paper the hemorrhage occurred immediately after birth. It has not been my fortune to see these early cases, but only those in children of from six to nine months of age, and in which syphilis evidently was a factor.

DR. E. H. SMALL, Pittsburg—At the meeting in Atlantic City I reported a case of this disease.[1] This baby, the first one, was born of apparently healthy parents after a difficult forceps operation. When it was 31 hours old I was summoned by telephone and informed that she had passed too much meconium and had thrown up some material that looked like meconium. The baby was seemingly all right on my arrival in about twenty

1. THE JOURNAL A. M. A., Oct. 27, 1900, p. 1084.

minutes. I went home and in a couple of hours there was another hemorrhage, both from the bowel and mouth. There were several more from the rectum in the next twenty-four hours of almost pure blood, unclotted, but no more from the mouth. The child became exsanguinated, her appearance being that of the last stage of cholera infantum. At one time she had a temperature of 104 and then went into a collapse. Notwithstanding this great loss of blood she eventually recovered. I saw, later, a similar case with hemorrhage both from the mouth and rectum. This patient died. Both parents were healthy, with several healthy children.

Shortly after the publication of my case in THE JOURNAL I got a letter from an old practitioner in Michigan, stating he had never seen such a case until about one year before. Since then he had had four cases of hemorrhage occurring in the first few days of life, the hemorrhage being from both the bowel and mouth. All these babies died, all were in the open country and the parents in each case were apparently healthy. I thus have to report six cases with but one recovery. In all of these, so far as I can learn, the parents were healthy.

DR. RUDOLPH W. HOLMES, Chicago—I used the gelatin treatment once locally on a boy eleven days old who bled persistently for twelve hours following a circumcision; there was almost immediate and lasting hemostasis. Twice I used the gelatin-salt solution subcutaneously for postpartum hemorrhage without untoward reaction. Lancereaux, one of the first to suggest systemic administration of gelatin solutions in hemorrhage, strongly condemned the intravenous injection on account of the danger of emboli. I would like to ask if it were not possible that a small subcutaneous vessel was torn during the injection, with the result that some of the solution was forced directly into the circulation, producing minute emboli, and the untoward symptoms. A short time ago I had a pregnant patient who gave a history of repeated postpartum hemorrhages in all her previous labors with grave symptoms. For about two weeks previous to her expected date of labor I had her eat twice daily generously of gelatin foods (jellies, puddings, etc.). The combination of these foods with calcium chlorid was of considerable benefit, at least the hemorrhage was nothing like what her previous attendant described. Later I found Dr. H. A. Hare recommends gelatin solutions and foods by mouth in hemorrhagic patients, as cooking does not deteriorate its coagulating properties. Would it not be in line to devise an appropriate infant food with gelatin for the cases Dr. Abt describes? Does Dr. Abt consider the so-called pseudo-menstruation of the new-born girl in any way connected with the condition under discussion? This pseudo-menstruation is not at all infrequent, occurring fully in 5 or 10 per cent. of newly born girls.

DR. A. JACOBI, New York—I saw a good many more hemorrhages in the newly-born thirty or forty years ago than more recently, and for one very simple reason, i. e., that at that time I saw a great deal more of puerperal sepsis than at present. Then it was a common experience to make an autopsy on the newly-born baby and find hemorrhages both large and small over the pleura, pericardium and the mucous membranes. At that time I took it almost for granted that the tendency to hemorrhages in the newly-born was very great. Since, however, puerperal sepsis has become comparatively rare I have seen very many less cases of this kind. There is no doubt in my mind that puerperal sepsis has a great deal to do with the hemorrhages of the newly-born. There is, however, another reason for hemorrhage in the newly-born: we should not forget that hemorrhage means a defect, not in the blood, but in the construction of the wall of the blood vessels. In many anemic women we meet with menorrhagia, and others with amenorrhea, all dependent on the structure of the blood vessels. The same reasoning is applicable to the fetus and the newly-born. Tissues are largely still in the embryonal condition, the tissues more fragile and the blood vessels burst very readily. When such a rupture has taken place we must take into consideration the state of the blood also. Hemorrhages in the newly-born are apt to be very extensive for the reason that although the blood of the newly-born contains more hemoglobin than in later life, its specific gravity is much less than in the adult and there is less fibrin. That is why when the hemorrhage once begins it is hard to stop it. Single hemorrhages into the sterno-cleido-mastoid muscle during birth may be copious. We frequently find meningeal hemorrhages extending all over, even down into the spinal canal. Another proof of the difficult coagulability of the blood of the newly-born is found in the fact that it remains fluid for a long time in cephalohematomata. Meningeal hemorrhages are frequent, being the cause of many deaths in the first week of life. I have seen a few hemorrhages about the medulla. I recall one case in which the baby moved a little immediately after birth, but within a few hours there was total paralysis of the four extremities. Diagnosis was made of gradual hemorrhage about the medulla, and a bad prognosis was given. Ice was applied to the neck and iodids were given internally, and the baby recovered. A few others of the same kind died and could be examined after death. Many of the hemorrhages in the newly-born depend on septic infections.

Some cases are certainly the result of antenatal sepsis. Oliver Wendell Holmes was the first to show that puerperal fever is contagious. Many believe that Semmelweiss, about 1867, was the first to prove the contagiousness of this fever, but I wish to insist that it was our own Oliver Wendell Holmes who, in 1843, wrote a very extensive paper on the contagiousness of puerperal fever, and proved absolutely that it was contagious and that it was carried from one patient to another by the attendants. Most of the cases of puerperal sepsis in babies are contracted after birth, but there are cases of antenatal origin in which the infection is carried from the diseased mother through the placenta, or through putrid amniotic liquor. In the newly-born the invasion may take place through big or small lesions of the integuments; that is, both the skin and the mucous membranes of the mouth or the digestive or respiratory organs; now and then, also, through the wounds of circumcision, or mastitis, or a maltreated cephalhematoma.

DR. J. C. COOK, Chicago—A child weighing ten pounds was born at full term and died of hemorrhage from the bowel only. The child born previous to this had died of sepsis at the age of three days. At this time the family were living in a house badly contaminated with sewer gas. There was no history of syphilis, and a healthy child had been born since in another house and no signs of hemorrhage or sepsis.

DR. FRANK X. WALLS, Chicago—The position taken by Dr Abt I think is excellent, i. e., calling these cases spontaneous hemorrhages of the new-born rather than describing them as examples of the hemorrhagic disease. These hemorrhages should be looked on as the result of an infection, or perhaps of an intoxication. In addition to the causes enumerated by the Doctor, I may add that malarial intoxication may possibly be a factor. I have seen one such case. In another case the baby had disease of the liver with obstructive jaundice, and the jaundice was the causal factor of the hemorrhage in this instance. In a case of spontaneous hemorrhage, in which the child vomited considerable blood, a microscopic examination of this vomitus showed that the blood was arranged in masses resembling exactly the blood casts seen in cases of hemorrhagic nephritis; in fact, some who saw the specimen thought it was one of urine from a nephritic. This would indicate that the hemorrhage comes not from emboli or from a single vessel, but from a diffuse oozing through the gastric tubules, the blood coagulating in the tubules and retaining the form of the latter. As an additional confirmation of this fact I may say that some of the casts were bifurcated. These cases very quickly disappeared, probably owing to the action of the digestive ferments.

DR. ABT—In reply to Dr. Holmes, I would say that I do not think I punctured the blood vessel, for the skin was loose and was picked up carefully, and I used a coarse needle, which could not have entered the lumen of a superficial vessel in the region where I was injecting. With regard to pseudo-menstruation, I suppose the doctor applies this term to the flow of blood from the vagina of the newly-born. This term seems to me to be a misnomer. We can not speak of menstruation in an infant whose generative organs are net yet functional. Hence, if menstruation is impossible, pseudo-menstruation must certainly be. The use of calcium chlorid has been warmly recom

mended for a long time, and, indeed, where one child has suffered from hemorrhage following its birth it is a good plan to give the mother calcium chlorid during subsequent pregnancies, and the same may be given to children after their birth. I think Dr. Jacobi struck the keynote of the entire subject when he said these cases were, first infections, and secondly, were dependent on a natural porosity of the blood vessel walls plus the fact that the coagulation of the blood in children is delayed. There may be delayed coagulability, brought about by some infection or some condition such as jaundice, as referred to by Dr. Walls.

CONSERVATISM IN THE TREATMENT OF ACUTE MASTOIDITIS.*

SARGENT F. SNOW, M.D.
SYRACUSE, N. Y.

Acute mastoiditis is a disease which has assumed an importance not to be gainsaid and is ripe for study in all its phases of pathology and treatment; surgically it can be so well handled that a conservative attitude should be taken only after a careful and full explanation to prevent being misunderstood; the author takes it more as comparative with the attitude of those who hold that in every case where there is evidence of mastoid involvement the external operation should be immediately performed.

A MIDDLE GROUND FOR TREATMENT.

The author also wishes it to be understood that by conservatism he does not mean inactivity, for the results of the waiting plan are replete with disaster. Ultra-conservatism in these cases is in reality a crime; cerebral complications are too grave to admit of anything but prompt and vigorous action.

The main object of this paper is to show that there is a middle ground for treatment, practically safe, based on well-established principles of drainage and prevention of pus developments. Major cranial operations, owing to frequent malposition of parts, anesthetic complications, etc., are too grave to be looked on lightly, and should not be done unless the conditions be urgent or the more conservative methods clearly out of place.

THE INDICATIONS.

Acute inflammation of the mastoid cells practically always comes from an extension of inflammation in the middle ear; this extension does not follow if free drainage is obtained early, hence a clear and forcible indication, which we may call our first, is to incise the drumhead promptly, not a simple puncture nor to rely on a small perforation made by Nature's attempt at relief, but to cut freely, as will be described later on. Drainage is as important here as in surgical propositions elsewhere and is the surest abortive measure.

Our second indication is to keep inflammatory action and pus development within bounds by cold or heat, a task often unsuccessful, not because the plan is irrational, but because the direction or nursing is insufficient.

THE TYMPANO-WILDS INCISION.

A red bulging drum is not the only guide as to the necessity for incision, as recently pointed out by Dench; severe pain or tenderness in a mastoid may necessitate prompt opening of the middle ear cavity, even though the drum shows no redness; this opening should be done freely, starting the knife near the lower margin in the posterior half, carrying it well through to the inner wall, up and out through the attic to bone tissue, cutting then deeply out along the posterior superior wall of the external canal. The latter portion of the incision not only drains the attic, but it relieves the periosteal tension at the point most needed, the lower wall of the mastoid antrum. This well-known paracentesis and internal Wilds incision becomes, in a measure, a subsitute for the more radical external operation by chisel and curette if thorough after-treatment be carried out.

In this connection allow me to call attention to the fact that very often the circulation is so much relieved by the opening thus made, that reparative processes close up a portion of the opening too early, so that we find tenderness, fever, etc., returning after one to three days, which is easily subdued by a fresh incision. Cold or heat will not avail unless drainage be free.

In neglected cases the effects of abortive attempts must be carefully scrutinized, and unless unmistakable improvement is noted within twenty-four to thirty-six hours the securing of a still better drainage is imperative; again allow me to say, that ultra-conservatism may become in reality a crime, and personally I wish to condemn such a position with all possible force. If the tympano-Wilds incision has not been thorough it must be enlarged or external operative measures instituted.

The plan outlined above which, as stated, is from a comparative standpoint conservative, has been advocated by the author at each opportunity since 1896. In a discussion before the American Laryngological, Rhinological and Otological Society in Pittsburg in 1898, I called attention to the great value of conservative methods and reported a severe case, showing the benefit to be derived from a prolonged and continuous application of cold, even beyond forty-eight hours where such treatment brought relief.

I was not alone in this, as following in the same discussion Myles of New York stated that he found, in examining his records, that by conservative methods of treatment, he had cured over one hundred cases, which, according to the rule of some men, should have been operated on.

In support of the conservative position, I can now also report forty-five consecutive cases, where I deemed it safe to try abortive measures, that I have recently treated on these lines without a failure, twenty of them being in private and twenty-five in hospital practice. These were acute in variety, but each case presented the indications usually laid down for the external operation, and each one, in my mind, had an undoubted involvement of the mastoid and pus in the cells of not a few.

NARRATION OF CASES.

If you will allow the time I will briefly report three cases:

CASE 1.—Mr. P., sent to the Hospital of the Good Shepherd by Dr. F. W. Smith, Syracuse, N. Y., June 16, 1899.

Examination.—Deep stupor, from which he could scarcely be aroused; could answer nothing intelligently and would at once drop into snoring sleep. Temperature, 102; pulse, 120; very free pustular discharge from the right ear, the auricle of which was pushed well forward by the swelling over mastoid. Pressure on the mastoid was about the only thing that would arouse the man to show that he had any consciousness.

Treatment.—The patient was admitted early in the afternoon, but, as my telephone communications were cut off, those in charge at once started the treatment of continuous cold and cleansing irrigations, until such time as I could be reached, which in this instance was late in the evening. When I visited

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. J. F. Barnhill, C. R. Holmes and G. H. Makuen.

the hospital, I thought that nothing but extreme operative procedures would avail, as he was still in somewhat of a stupor, from which he could only be aroused to say yes or no; but as the temperature had dropped two degrees, and the pulse thirty beats, from the treatment they had started, I simply cleared out the ear, enlarged the perforation in the drum, cut out along the superior posterior wall as above described, and left him to the care of the nurses, with definite, explicit directions about keeping the local applications of ice constant and the canal free.

The next morning I visited the hospital early, prepared and expecting to operate externally, but found the patient conscious and so decidedly improved that such a procedure was not to be thought of, and I am happy to say he went on to a complete recovery.

This case is reported more to show what prompt, intelligent nursing can sometimes accomplish than to amplify the fact that such severe cases may at times recover. As a rule, it is my habit to do the external operation in such extreme cases, and I hope no one will infer that I advocate conservative treatment in cases showing such evidence of cerebral complications; in these there appears no safe rule except to immediately open and clear out the mastoid.

CASE 2.—Dr. C., a veterinary surgeon, brought to my office by Dr. D. H. Murray, Syracuse, giving history of acute pain, swelling, etc., behind the ear with some discharge for five weeks.

Examination.—The temperature, tenderness and infiltration of the tissues behind the ear were also intense, pushing the auricle forward to a right angle with the head, making the typical picture of a bad mastoid case.

Treatment.—I at once made the internal incision described and sent the patient to the hospital, where he was treated in the thorough manner that such cases demand, with the result that in six days he was able to leave with the drum healed, all tenderness removed and no rise of temperature or pulse. The patient assured me that during this period there had been no moment between the time he entered the hospital until he left to come to my office, when the temperature of the mastoid tissues were allowed to get above that obtained by the ice-bag application. The cold was continuous and persistent.

CASE 3.—Miss H., age 18, brought to the Hospital of the Good Shepherd by Dr. Countryman, Central Square, N. Y., May 25, 1900, who stated that the ear trouble had followed an attack of scarlet fever six weeks previously, and that the pain, tenderness and swelling had been present behind the ear for two weeks.

Examination.—Thick purulent discharge, tissues over mastoid much swollen, the diffuse inflammation almost closing the external auditory canal. The whole right side of the head and face so swollen that eye was closed. Temperature stood at 102, pulse 120, and the patient was suffering intense pain in the ear and mastoid.

Treatment.—Dr. Countryman had immediately brought the girl to the hospital on the case coming under his care, hence he had instituted no measures for relief, so it was thought best to do paracentesis and the internal Wilds incision and apply ice, watching the case carefully. Next morning her temperature had dropped to 99, pulse to 90, and the patient made an uninterrupted recovery, the drum healing in five days, but pus continued to come from the incision in the superior posterior wall for two weeks.

The selection of Cases 2 and 3 from my records is because they represent so well the types of uncomplicated mastoid inflammation, on which my conclusions are based, and were each referred by well-known men, whom I know will let no improper claim on my part go unchallenged, but in no such would I consider it safe to adopt these more conservative methods of treatment under the operator remain within easy reach.

It is not always possible to get such quick and absolute recoveries, as I found in treating a series of cases that accompanied an epidemic of influenza that we had here in the winter of 1901. Several of those had a purulent discharge lasting from three to six weeks, but in all my practice there has never been left a chronic otorrhea except in one case, where an anemic lady, aged 68, who left town as soon as a recovery from active symptoms were brought about: even now her discharge is so slight that, on a recent visit to the city, she did not come in to see what could be done about it until the last day of her stay.

THE ESSENTIAL DETAILS OF THE AFTER-TREATMENT.

Sufficient nurses, giving faithful care, are most essential factors in the conduct of these cases, and their intelligent co-operation explains why one man gets so much better results than another, from apparently the same line of treatment.

With the nursing ordinarily given mastoid cases in private families, or even in our hospitals, I would feel no safety in relying on the conservative methods described; but where the free drainage is secured and conscientious nursing is rendered, with less than a five-minute interval between ice bags, we seem to almost always get prompt effects.

Ice should be kept on continuously for hours, the object being to drive the blood from the part, and it is much better to keep it out than to have an interval of recongestion, as will occur if the nurse be slow in refilling the bag. Intense heat may be used with benefit, if the nurse display the same energy, though I prefer cold, and find that by employing a little tact it will be tolerated by the most sensitive; the steady, persistent application of either of these measures keeps the blood vessels contracted, which condition allows Nature good opportunity for resolution and repair. If such expert nursing and attention can not be given, external operation becomes the safest and only procedure.

As stated before, I am not alone in objecting to the wholesale chiseling now in vogue, though this may be the first paper dedicated to conservatism, neither am I alone as to the utility of keeping the parts at a low temperature. Richardson of Washington read a paper before the Laryngological, Rhinological and Otological Society last year, in which he pointed out the great value of continued and prolonged ice applications in the treatment of this disease.

At the very least, we should institute the abortive measures in that interval that usually exists between the time when we first see or have charge of a patient until the final preparations for operative work are made. If we leave the case to ripen we will surely find pus and softening. These abortive attempts in my practice have never done harm, and I feel certain that if the work and nursing are thoroughly carried out, over 50 per cent. of the external operations can be avoided. There are too many cerebral complications, too many histories of infected lateral sinuses necessitating ligation of the internal jugular four or five days after the external operation, to warrant us in taking unnecessary risks. While skilful, experienced men obtain an acute tactile sense that tells them when instruments approach dangerous ground, the less experienced make many blunders; what is really a trivial operation with the one man becomes with the other fraught with much danger.

The objection that the Sprague ice bag, like opium, masks the symptoms, in my opinion, need not be entertained if free drainage has been established. The relief we get from its use in reality indicates a lessened morbid activity, and if acute symptoms do super-

vene, it is because our drainage is being obstructed. Extension of inflammation is hindered, because ice, here as well as elsewhere in the body, seems to prevent development of pus elements. In fact, with free drainage and good nursing I find that I rarely have to resort to the external operation except in neglected cases, or in those associated with a chronic otorrhea.

The reason why these inflammations invade deeper structures is because there is pressure; if we relieve this pressure promptly by letting out the blood and pus confined within the middle ear and mastoid antrum by what I have called the tympano-Wilds incision, we have taken the first important step. If we maintain this free drainage, modify the development of pus elements by constant ice application, and keep this treatment up as long as improvement follows, the danger of intercranial involvement is reduced to a minimum.

Continued and increased experience more than fortifies me in the position taken in 1896 and lends me courage to again advocate conservative but prompt treatment along the lines above mentioned, in acute cases without cerebral complications.

707 University Block.

DISCUSSION.

DR. GEORGE L. RICHARDS, Fall River, Mass.—I have just had the misfortune, the first time in several years, to lose a mastoid case after following out the lines the essayist has advocated, and I would rather operate thirty times unnecessarily and save my patients than to be a so-called conservative and lose one. In the case I referred to, free paracentesis was done, the icebag was applied, pain disappeared, temperature became normal and the case apparently improved, and the young man went out of the hospital and returned to work. He appeared at the hospital five days later with symptoms again present and pus in each mastoid. Although several operations were done and both the dura and the sinus uncovered, the patient developed meningitis and died. This question of conservatism is one the general practitioner always has in mind, and he is usually so conservative in the first place that he will seldom let us operate early enough. We should operate just as soon as there is tenderness behind the ear, and any considerable edema or other symptoms pointing to purulent or serous mastoiditis. There is risk in waiting until to-morrow, as we are often compelled to do, especially by the physicians in the smaller towns. In reference to the application of cold, I will admit that it apparently improves the symptoms, and the patient seems to feel better for the first few hours after its use. It has recently been held that the application of cold only drives the process deeper in and masks the symptoms. The fact that some cases get well is not a conclusive argument in favor of such conservatism as the essayist advocates. We should not pursue a course of treatment that is not surgical in the presence of a purulent process. My case happened to be a serous case, probably due to the pneumococcus, and I do not suppose any treatment would have saved him. Nevertheless I afterward regretted that I had not opened the mastoid at the first suggestion of trouble. I entirely agree with the Doctor's method of paracentesis, which is undoubtedly the best. But in the presence of mastoiditis, the bone should be opened as soon as the diagnosis is made.

DR. W. L. BALLENGER, Chicago—I agree with Dr. Snow's method of paracentesis. If you are going to incise the drumhead at all, do it freely, carrying it to the upper and posterior wall of the meatus. I arise especially, however, to speak against the general trend of the paper. I do not believe it is safe to recommend so simple a method of treatment for the cure of such grave cases as Dr. Snow has reported to us this afternoon—not but it cures many of them, but because it will not cure some of them, as Dr. Richards has pointed out. When cases come to us with grave symptoms, who have had, some years before, some one of the exanthematous fevers followed by acute mastoiditis, which apparently recovered, they may become at a later period among the most grave conditions coming under our observation. I do not believe it is wise to advocate, in print at least, such conservative measures as the Doctor has advanced this afternoon, for the reasons Dr. Richards has already pointed out. A study of acute suppurations in general of the middle-ear will show how readily the process becomes a chronic one, often when there are no symptoms that the patient can observe. They often tell us that there is no discharge from the ear, whereas an examination will show pus to be present. That is one of the most common experiences I have in my clinic. So we can not trust to the statements of the patients that they are cured. The forty cases reported by the Doctor will probably not give 100 per cent. of cures, as he has reported. In a few years probably 25 per cent. of them will show a return of the disease. So I would object, not to the treatment but to the statement that it is a method of treatment that will cure a large percentage of the cases which we now think should be operated on by the post-auricular method.

DR. C. M. COBB, Lynn, Mass.—My experience is that the cases with swelling and perhaps involvement of the superficial mastoid cells are the cases that you can most safely treat by the so-called conservative method, but the other cases you can not. I recall a case that was free from pain for five weeks, and I began to believe that he was getting better and that he would not have to have a mastoid operation. There was no swelling, no fever and no pain. He did not hear very well. He came to me then with a swelling above the temporal ridge, and I recognized a perforation under the temporal fascia. My experience with those cases is that if they show swelling above or around the ear, extending to the face, they have either a perforation of the cortex or an involvement from a lateral sinus thrombosis and they need surgical treatment. Surgical treatment may not always save their lives, I know, but they die if you do nothing. A collection of pus under the cortex in the mastoid is not a thing with which we can afford to temporize in any way.

DR. J. E. BROWN, Columbus, Ohio—Dr. Snow's paper well sets forth the strength of conservative treatment. We should bear in mind, however, that cases treated conservatively frequently relapse. Not only may they furnish cases of chronic middle-ear disease later, but they may be subject to early relapse, this coming on three or four weeks after the original disease. The fact, too, that in many of the cases which come to operation where symptoms have been few and obscure, we find extensive and serious involvement of the tissues, makes conservatism sometimes dangerous. The class of cases represented by the first one reported by the essayist is one in which we can not hold that it is safe to delay operation. The Doctor achieved a cure in this case, yet taking a large number of cases presenting exactly similar symptoms, I do not believe that even a fair percentage of such cases would be cured by the same line of treatment. I believe the experience of otologic surgeons to-day demonstrates plainly that the greatest safety to the patient lies in prompt operation.

DR. A. H. ANDREWS, Chicago—The position of Dr. Snow is, I believe, to say the least, dangerous. It has occurred, no doubt, in the practice of all of us to have cases get well under such treatment, or under even less radical treatment than he has indicated or even without any treatment at all. Perhaps a considerable number will get well without treatment, but that does not prove that we should not treat them, by any means. Pus travels in the direction of least resistance, and as one of the gentlemen said, in discussing this paper, we might temporize with those cases in which the swelling was superficial. The cases of mastoid disease without superficial symptoms are far more dangerous. If we agree at all with Dr. Snow's position, we ought to make a more definite distinction between those cases which are primary and may be treated as Dr. Snow suggests, and those cases which have had otitis media before, or in which there is any possibility that they may have had otitis media before. If there is a history of repeated attacks or that this is a second attack, no such treatment is permissible. Some of us who practice in the larger cities come to think that Nature is not so kind to our patients as she is to those under more favorable circumstances. I do not believe that the treat-

ment which Dr. Snow advocates and which has seemed to be so successful in his hands, would bring about the same results with the patients I have to treat, especially my clinical patients.

DR. L. C. CLINE, Indianapolis—If I should ever be so unfortunate as to get an abscess of the ear and it confined itself to the tympanic cavity, I want Dr. Snow to see me, but if it travels and gets into the mastoid cells and antrum, I want Dr. Richards to see me. I think much depends on our diagnosis. If we are able to diagnosticate these cases we will be better able to determine on which to operate and on which not to operate. I think, however, the advocacy of Dr. Snow's position to the profession generally is a dangerous thing. The majority of physicians are opposed to these operations. They are extremely conservative and occasionally, when I think it is absolutely necessary to operate, I have difficulty getting permission to operate until it is perhaps too late. It seems to me it is safer, in this instance, to err in over-operating rather than under-operating, until we get the practitioners of the country posted or educated up to the point that they will permit us to operate. So much depends on our ability to observe the cases and determine the diagnosis. If we have pus in the mastoid cells we should do just as we do when there is pus in the appendix. If we err at all, we should err in the direction of early operating.

DR. J. F. KLINEDINST, York, Pa.—I have tried the treatment outlined by the Doctor in a number of cases. I believe it is a good one in early cases, but if we do not see the cases early, it is advisable to open the mastoid cells. There is one therapeutic measure, to which the Doctor has not called attention, which I believe does good in many early cases, and that is local bloodletting, by either the natural leech or the artificial leech. As to the use of cold, I recall the case of a boy about 5 or 6 years of age. The case seems to show that sometimes the general practitioner wants to be too conservative in these cases, simply because he does not understand the pathologic changes that take place. I advised this physician, when his boy was taken sick, to allow me to incise the drum-head freely, but he refused to have it done. Then we kept ice on for forty-eight hours, almost continuously. There was considerable tenderness over the mastoid and some slight edema. Fortunately the case got well, while I was continually urging that the mastoid be trephined. It was one of those lucky cases that get well under the application of ice when you are almost sure there is pus forming in the mastoid. In chronic cases of purulent otitis media with acute mastoiditis trephining ought to be done, because in them there is pus gathering in the mastoid cells, producing the secondary inflammation and infection.

DR. G. MCAULIFFE, New York City—There is no doubt that the cases to which Dr. Snow's treatment is applicable are those in which the process is limited to catarrh. I do not find the treatment has been successful in cases in which there is pus in the mastoid cells. The principal danger in operation as urged by the Doctor is the infection of the sinus. This has often been opened without any special symptoms. The general run of mastoidites are so septic that nothing short of a radical mastoid operation should be considered. The thorough bloodletting, which occurs during the operation, is one of the best methods of depleting the mastoid. All our cases of sclerosis have arisen from treating the cases by so-called conservative methods. The conservative treatment gives us some of the most difficult secondary operations in mastoid surgery. I find, in regard to drainage, there is no drainage so poor as that derived from the so-called internal Wilde incision. The antrum keeps taking a lower and lower position in aural development. As age goes on it gradually sinks down back of the posterior wall of the canal. The pus can gravitate into the tympanum only when the patient is in certain positions. The antrum is the last thing in the consideration of the disease. When the stellate cells are involved in the floor of the antrum and the cells that are shut off from the antrum by the layer of compact tissue that forms a shelf over the lateral sinus, how is any incision in the tympanic cavity going to drain the granulation tissue or pus here? Many of the best things in mastoid surgery have been gained from general surgery. There is nothing better than good counter-drainage. The antrum has always been regarded as part of the middle ear and does not come into consideration in studying the mastoid. The hearing is better after the operation and connective tissue changes less.

DR. P. J. GIBBONS, Syracuse, N. Y.—In Hippocrates' time and until after Galen we had radical treatment. Then the treatment was conservative until about twenty years ago, since which time we have again been radical. I know Dr. Snow does radical work, just as the rest of us do. It is important that we remember our internal medicine and not consider mastoiditis a local disease. Often there is back of it a constitutional condition. In the way of therapeutics we have internal medicine and local medicinal agents, such as the suprarenal extract. But if you do not open the mastoid cells you will regret it, as you would if you did not open up the skull by trephining; but you will never regret having operated. These should be treated as surgical cases. We should also consider the internal medicinal treatment of these cases and what the sinuses are there for. The mastoid cells and the sinuses throughout the head serve both to lighten bone and to increase the hearing. They probably also have some effect on the ions of the blood. You will find the "rheumatic diathesis" we are jumping into is a big boat-like "malaria" and the "grip." Such diseases may be due to trouble of the sinuses. Dench and a number of recent writers have been radical, and for some twenty-five hundred years we have had conservative treatment. But Dr. Snow's paper will probably be misunderstood, especially by the laity. No doubt the Doctor is misunderstood here. It is a dangerous paper for the general practitioner, and especially so for the laity.

DR. NORVAL H. PIERCE, Chicago—It is probable that Dr. Snow has been misunderstood, for we all know that he can be as radical as any one of us, and, therefore, in order that he may set himself aright, I would like to have him state what he believes to be the proper indications for opening the mastoid in acute cases. Operating in this region is an easy matter for one skilled in the technic, and it is exceedingly hazardous for one not so skilled. The antrum and the mastoid cells are connected, and suppuration in these parts may get well without operation. Softening of the bone in the presuppurative stage may recover without operation. But if we have a case in the sixth week of inflammation, with a temperature of 102, with swelling of the posterior superior quadrant of the membrane and infiltration over the mastoid region, and if it is said that such a one is a proper case for conservatism, then I would like to ask, when should we operate? How frequently have I cut down on these cases, not only with such symptoms, but cases going on for five or six days with slight pain and no infiltration and a slight purulent discharge from a perforation in the posterior superior quadrant, and found the whole bone necrotic, the sigmoid sinus uncovered and the tables of the skull open by the necrosing process. We would find, within 24 hours, perhaps, sigmoid sinus thrombosis and meningitis. I think Dr. Snow must set himself aright, for the impression I get, at least, from his paper is contrary to modern teaching and is dangerous if allowed to proceed.

DR. SARGENT F. SNOW, Syracuse, N. Y.—Perhaps the best way to answer the many men is to begin with the last speaker. Dr. Pierce asked when I considered it proper to operate on the mastoid. I will answer that by saying that if our patient comes to us with evidence of intracranial involvement it goes without saying that we must operate as early as possible. That is, of course, one indication. Then, again, if we have a patient that gives a history of recurring inflammations, recurring attacks of these troubles that have been neglected, we are often forced to operate externally. But if the patient comes to us with an acute inflammation, though he may have badly swollen tissues over the mastoid, though he may have the auricle extending forward, with severe pain and perhaps high temperature, if it is an uncomplicated case and primary, we are very safe in making the incision and applying ice as I have described for the first 12 to 24 hours. If our patient then shows no improvement, but shows a condition a little worse, perhaps, or even the same, we must use great care about going further in our conservatism. I do not advocate making this internal incision, applying ice and waiting indefinitely. We must have

good drainage and definite results from it or we must operate externally.

Dr. Richards speaks of the effect of this paper on the general practitioner, and I quite agree that it would be unfortunate if this paper should create an impression among the general practitioners that we would tolerate anything but prompt, vigorous action. I have tried to use the best language to impress the idea of vigorous and skilled action. There must be no half-hearted attention, and we must not allow our nurses to be negligent. The cases must be watched with great care. I go into these cases, even in the mild ones, with a great deal of trepidation, for I recognize their gravity. But my experience is that if we do this work promptly, on the cases that come to us reasonably early, not those so far along as the ones I related, we are safe in a conservative attitude. How many of us operate the same day, any way? There is usually an interval before operation, and we ought to use that interval and make our first visit count. Secure drainage and put on the ice. If we leave the case 12 to 24 hours without proper care, with only the drainage that Nature gives, it will ripen into a worse condition. If the nurse applies ice after free drainage you will get the same results I have, but it must be kept on continuously, without marked intervals in the changing.

As to doing the external operation on every case where there is swelling and tenderness over the mastoid, I must again say that I do not believe it is justifiable; if we give them a chance they come out without operation. As to the question whether we can cure a large percentage or not, I would reply that in my opinion over 50 per cent. of the primary cases now operated on externally can be handled in the way I have suggested. Dr. Cline thinks the difficulty is with diagnosis. It is very possible that I have made some mistakes and that I have not had pus in the mastoid in some cases, but I have not reported any cases but those in which there were well-marked evidences of pus with tenderness, swelling and pushing forward of the auricle. The principal point to be borne in mind, if we use the conservative plan, is that we must select the cases that come to us early, have our incision free and know that our nurses thoroughly understand their duties.

TREATMENT OF CHRONIC PURULENT OTITIS MEDIA.*

D. A. KUYK, M.D.
RICHMOND, VA.

When we take into consideration the vast number of people, both children and adults, who suffer from chronic suppurative ear disease, the greater majority of whom will allow their disease to continue and progress, thereby courting disaster and perhaps death, rather than submit to operative intervention, it behooves us to endeavor to study out some plan of treatment other than the surgical for the relief and cure of these sufferers, and any time given to the study of this subject is time well spent, for we then fulfill the task to which we have dedicated our lives—namely, the relief of suffering humanity.

The relief and cure by conservative essentially non-surgical methods of a large per cent. of these cases is not only probable, but highly possible, and if we can give these patients a fairly hopeful prognosis very many more of them will submit to treatment and be saved from the imminent danger to which they are continually exposed and from the mistreatment applied by themselves, their friends and the army of quacks who prey on the mental and physical sufferings of all the human family who are the victims of chronic affections. If the conservative treatment of chronic purulent otitis media presented a large percentage of failures; if the benefits of this treatment were but temporary, or if this treatment subjected the patient to even the slightest danger, I should apologize for trespassing on the time of this Section by the presentation of a paper on this subject, but the results of this treatment, as used for the past six years, have proven so satisfactory and continue to be so good that I can not refrain from giving expression to the faith that is within me, and plead with those who differ from me to give these cases more consideration, more time, more patience and more conservative treatment before resorting to the radical surgical measures, recommended as the only positive cure for this disease, which are not only distasteful to the patient, but are not so invariably successful as to enable one confidently to predict a complete and permanent cure.

True it is that when a patient comes for treatment who has had perhaps for years a purulent otorrhea, foul smelling and profuse, we can not look within the middle ear and definitely ascertain the extent of the process or the condition of the structure involved, yet it is about as exact as our actual knowledge of the condition of the internal organs of the body when they are diseased, yet they are successfully treated and the patient cured; it does not therefore so much matter that our treatment must be largely symptomatic. Experience and observation teach that it is quite possible to accomplish much good in these cases, very often completely and permanently to cure them, without resorting to radical surgical intervention.

Naturally, most patients shrink from surgical operations and are often permanently frightened away by dogmatic insistence that the mastoid operation, more or less radical, alone offers any hope. If now we can suggest a plan of treatment essentially non-surgical and more in consonance with the patient's preconceived ideas, that offers a fair chance even for the cure of the disease, the patient readily submits to treatment, and in the event that this treatment fails to effect a cure the patient is then in such a frame of mind that the only remaining alternative—surgical intervention—is accepted without fear or hesitation, we will have done the patient no injury by the time given to the trial of the conservative treatment, but we will have created one of our greatest aids to a successful termination—a calm and composed mental condition and that of unalterable confidence in the surgeon. Then, too, the treatment is popularized and more patients will present for treatment by a method that is essentially non-surgical and to them seems more humane and which certainly is to them less fearful and often, very often, productive of the most beneficent results.

Because now and then an anomalous case is seen in which, while the symptoms are very insignificant or are very much masked, the pathologic changes are found to be profound and extensive, it does not vitiate my plea for conservatism, for such cases are rare exceptions. Should we, however, at any time deem an operation imperative we have the patient under our immediate observation and can institute whatever procedure is deemed best rather than have the patient judge for himself, as so many of them will do, when not under treatment; in fact, they often insist on doing so, anyway. Before going further it is, I hope, thoroughly understood that in the cases selected for conservative treatment there must be no evidence or indication of mastoid involvement, for this would at once exclude every form of treatment other than the surgical. Permit me briefly to give some results of this treatment in a few cases without presenting tables of exact figures.

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

In one case—in my own person—the ear has remained dry, free from all pain, comfortable and with fair hearing power—though suppurating and at times excruciatingly painful for fifteen years—for the last eight years.

Several cases have gone for five and six years and to the present time have had no recurrence. A considerable number have passed the last three or four years without further trouble. A greater number have for two years past gone on in comfort and still more for the twelve months past. The vast majority of these cases retain good and useful hearing. True, a few cases that lacked moral courage and persistence, or who would not obey instructions, discontinued treatment, but their last state was not one whit worse than their first, rather better. At least five cases, three tuberculous adults, and two children with inherited syphilis, made no improvement, and had to have the classic mastoid operation.

Before going further permit me to make confession to a sin of omission, namely, the microscopic examination of the aural discharge, but when one is fatigued with the duties of the day there remains little inclination for additional and fatiguing work. It is hardly necessary for me to say that one must ascertain as nearly as possible the existent condition of the ear or ears, also that of the nostrils, the various sinuses, the throat in all its divisions and the eustachian tubes (not forgetting the systemic condition), and removing all that is pathologic.

Now, any course or method of treatment which is inflexible, which is dogmatically and persistently pursued in each and every case alike of this affection, or, for that matter, in any disease to which human flesh is heir, must necessarily fail in many, I think I may safely add in a great number, and then the course or method advocated falls into disrepute in one's own mind, with the professional men who give it trial, and with the patients who submit to the treatment.

One may have predilections for a certain line of treatment, but they must often be surrendered to the requirements of the case. Treatment, indeed, should and must always conform to the needs of the case rather than the case conform to preconceived ideas of treatment. We must learn to discard at times our idols, dear as they may be to the professional heart. When this is done then will we obtain that happy consummation so much and so devoutly desired.

Necessarily the first procedure in the treatment of purulent otitis is the cleansing of the ear, and even on this apparently simply operation there exists a vast diversity of opinion. Yet so important is the manner of its performance that on the method of cleaning largely, I believe, depends the success or failure of the case.

The absolute dry method is employed by the writer and by him advocated; only in very exceptional cases is water employed, and for the reason that the frequent and long-continued and often forceful syringing employed by the surgeon and the patient in the first place liquefies the dense, heavy and ofttimes semigelatinous purulent or mucopurulent secretion, this liquefaction plus the force used with the syringe filling the middle ear, thereby producing more or less distension by reason of more or less pressure, favors percolation through openings into practically hidden and uninfected cavities or areas, the syringing ceases, the pressure falls, the perhaps only slightly distended tissues collapse and the infected fluid remains behind, leaving the germs on an ideal moist and warm breeding ground, where they multiply and carry on with unceasing and relentless vigor their pernicious poisoning processes. In the second place, the syringings cause maceration of the epithelial lining of the external auditory meatus and also of the middle ear cavity, the tissues become literally waterlogged, white and bloodless, hence of greatly diminished vitality and lessened resistance, rapid desquamation ensues, aggravating and prolonging the purulent process. In the third place, more or less liquid is left stagnant and infected within the middle ear; this not only does harm, but dilutes and renders ineffective any after medication that may be employed.

All visible secretion is removed with dossils of dry absorbent cotton, the Siegle otoscope is then used to aspirate the secretion from the hidden recesses of the middle ear, the quantity of the retained secretion is then estimated and its character determined; this process is repeated until the middle ear is free and clean and each time the secretion is removed with dry cotton. This aspiration is valuable because it increases the circulation of the middle ear, increasing its blood supply, so revitalizing and rebuilding diseased and destroyed tissue.

Next, a current of compressed air at moderate pressure is passed into and through the middle ear, usually through the eustachian catheter, and now, if the auscultating tube is used we can ascertain if any secretion still remains in the middle ear; if any secretion is forced out this is removed as before and the air current again injected and all moisture even is evaporated. We can combine with the air current a stimulating vapor such as iodin or any medicament we may select. It is of the greatest importance to get the entire aural tract dry, for we are then absolutely sure that all of the purulent secretion is removed; besides, the passage of the air current seems to stimulate the sluggish circulation and greatly aid the reparative processes; then, too, any medicament we may select is absolutely sure to come into contact with the diseased membrane undiluted by retained secretion or by the water left within the ear after syringing, and we can reliably depend on getting the full effect of the drug.

A few cases of chronic purulent otitis were treated by this cleansing process alone, using no drug or other means to modify the course of the disease, and most excellent results were obtained, but it necessitated more time and more treatment than the cases which were medicated after drying.

The patient is taught to pursue the same method of treatment at home, excepting the pneumatic otoscope; some cases employ that instrument also, substituting for the compressed air some form of nebulizer. A not very expensive apparatus is a bulbous glass vaporizer having a rubber air bag attached to it. This procedure is repeated twice a day; if the discharge is very profuse, oftener.

Adults are instructed to carry absorbent cotton in a box in the pocket, and so soon as any secretion is felt in the aural canal to remove it with a dossil, and repeat until the ear is quite dry. This is preferable to the gauze or any other kind of wick to drain the ear, for too often the wick is left in the ear too long and maceration and desquamation result, just as after syringing.

Of course, in treating children our methods must vary with the nervous temperament of the child, but most children quickly finding that no pain is inflicted and that comfort follows, will submit to all the details almost as well as the adults. The entire ear canal and whatever of drum membrane and ossicles is left, also

parts of the middle ear, can be now leisurely and accurately inspected.

Small perforations must, of course, be sufficiently enlarged to ensure free drainage—this is the great and all important essential to a successful termination—granulations or polypi removed or destroyed, necrosed ossicles removed, denuded or necrosed bone carefully curetted. If the eustachian tube is strictured it must be dilated until it is freely open, if this can possibly be done—for free drainage is as necessary within as without. If it is found in a state of catarrhal inflammation, as is evidenced by the peculiar inodorous gelatinous secretion, effort must be made to remove it by aspiration through the eustachian catheter rather than by blowing it out through the auditory meatus.

The cleansing process in an adult patient requires about fifteen minutes, rarely more, but it is time well spent, and though a troublesome one, is repaid by the good result usually obtained.

The host of drugs and combinations of drugs recommended is proof conclusive that we have not yet found a specific for purulent otitis media.

To fulfill the indications we must employ a drug that possesses powerful antiseptic and astringent properties and yet be stimulating. We need not go to the modern chemist for some synthetic chemic product that will supply our need, for we have an old, time-honored and well-tried drug that has never failed to produce the effect desired if only we learn to use it strong enough and often enough. Nitrate of silver is a drug that possesses undoubtedly the threefold function of an antiseptic, an astringent and a stimulant, as witness its good effect in gonorrheal ophthalmia or in ophthalmia neonatorum if it is used in sufficiently strong solutions.

Who is it that has done any eye work who has not seen the profuse virulent secretion of either of these ophthalmias melt away and become innocuous, the intensely congested and swollen conjunctiva promptly recede within normal limits by the application of silver nitrate solutions. Likewise will it affect the vast majority of chronically suppurating ears if first we remove all secretions and then dry the ear in all possible parts with the air current to avoid neutralization of the silver nitrate by the formation of an albuminous coagulate and thus fail to get its beneficial effect. A solution of thirty grains to the ounce is the weakest begun with; the solution is instilled comfortably warmed into the external auditory meatus, care being taken that none of it gets on the face or on the clothing, then with the otoscope the solution is gently and slowly forced into the middle ear so as to allow the solution to come thoroughly into contact with all parts of it, the pressure is steadily maintained for a few moments, then again increased so as to coax the fluid to go still further down into the eustachian tube; the moment the fluid reaches the throat the otoscope is removed, the patient holds the head inclined for a minute or two, any excess of fluid is removed, a dry cotton plug is inserted. This completes the treatment, which is repeated tri-weekly.

If after two weeks' treatment there is no amelioration of the discharge or of odor a solution of sixty grains silver nitrate to the ounce is substituted for the weaker one, so the strength is increased until a one hundred and twenty grain solution, the strongest that has yet been used, is employed. Occasionally the ear after several instillations of the silver solution will become sore and sensitive, when the use of solution is withdrawn and bismuth formic iodid powder is insufflated and forced into the middle ear in the same manner as was the liquid.

The bismuth formic iodid is strongly antiseptic, deodorant and astringent and certainly promotes cicatrization and is hence a useful agent in this disease. When the ear becomes quiescent the silver solution is again employed. The patient between treatments uses nothing but dry cotton to keep the ear clean and the nebulizer to dry the moist mucous membrane and endeavors by frequent use to keep it so. I always insist on careful and thorough home treatment, explaining to the patient the necessity and importance of the procedure and of thoroughness in its application.

Even after all discharge has subsided I still insist on the use of the air douche, medicated or plain, to be used at first once or twice daily, then twice weekly, and so to be continued for an indefinite length of time until the mucous membranes regain their lost vitality and become strong and non-secretive, remaining perfectly dry without artificial assistance. There are some cases which demand more than the mere office treatment to keep the ear aseptic, and, indeed, there are some patients who are not satisfied unless they are themselves dropping something into the ear, and to these I give a preparation consisting of menthol, camphor, formalin, hydrogen dioxid and alcohol, known as menthoxol, diluting it with equal parts of glycerin; this, after the ear is dry, is used in the same manner by the patient as the silver nitrate is used in the office, substituting the finger for the otoscope; the additional use of this mixture gives us in some cases most excellent results when the nitrate alone is insufficient. When four or six weeks of this treatment produce no amelioration of the symptoms we must conclude the disease process is too extensive or the bone necrosis too great to expect benefit from anything short of surgical measures, and such should be resorted to without delay to prevent the dangers with which all otologists are so well acquainted.

Yet, I still plead for more conservatism in the treatment of these cases, feeling convinced that many, though suppurating for years, have but limited areas of chronic suppurating membrane, easily and successfully treated and thus spared the major operation.

It is, however, our plain duty to study each case impartially, without fear or favor, laying aside our predilections and our prejudices and working only for the welfare, immediate and remote, of the patient who entrusts his case and perhaps his life to our care.

When we shall have learned to conquer ourselves for the benefit of our patients we shall be greater than him who conquereth a city, and our patients will rise up and bless us.

DISCUSSION.

DR. GEO. L. RICHARDS, Fall River, Mass.—In the main I try the dry treatment for a long time, or some similar method, before resorting to anything radical. You may take one of these suppurative ears and clean it out by the dry method and then, for a sort of experiment, syringe it out and you will often be surprised by the amount of debris that will come out. So it is questionable how well we are able to clean them by the dry method. In my own practice I invariably wash them out the first time and then use the dry method. Especially when there are one or more perforations, it is questionable whether you can get them clean by the dry method. Gauze, I think, is better than cotton for drainage, for it acts more like a lamp wick than cotton does and facilitates drainage better.

DR. A. H. ANDREWS, Chicago—I have sometimes been surprised, not as Dr. Richards has been, but at the amount of pus and debris which I could wipe away after the ear has been thoroughly syringed. I want to agree with the treatment given by Dr. Kuyk; I believe it is good and that there is no better

routine treatment. There may be occasional cases in which it will be necessary to syringe or to medicate in other ways, but I agree with his treatment in the main.

DR. G. V. WOOLEN, Indianapolis—No suction at all is required to remove the fluid. If there is anything that has been determined it is that hydrogen dioxid is a cleanser. You cleanse the ear, not with a syringe, for it would be just as bad as this suction to use a syringe on such an ear, but take an ordinary alkaline spray, such as you use in the nose, and spray the ear gently, mop it as the Doctor has suggested, if you can, without touching the hole in the tympanum. I think it was Dr. Randall, in Philadelphia, who said that there is nothing more difficult than to measure the distance in the ear, in doing probing or mopping. Next let the patient lie down; fill the ear with a 25 per cent. solution of peroxid of hydrogen and let that do its work. After securing the destructive action of this remedy on the pus corpuscles and dirt, we may wash it out and repeat. Continue its use if necessary for an hour, or until the bubbling ceases. The patient can tell you that he hears the bubbling sometimes even after it may no longer be observed in the meatus. I wonder oftentimes how and why it is that men, who know as much as physicians, are so afraid of moisture, so afraid of the water that God has given them so abundantly. They are so afraid of lacerations and all such things. After the hydrogen dioxid ceases to bubble, I like to use a solution of bichlorid of mercury, 1 to 1000. Then there is another remedy I like very much. It is boracic acid. One year we hear a remedy or method of treatment extolled very highly and the next year it is knocked to pieces; the next year it reappears, to be knocked down again perhaps the following year. But I know nothing better than to blow into the patient's ears boracic acid after the above treatment and let the patient go home well pleased.

DR. G. MCAULIFFE, New York City—In the treatment of otitis media we ought not to forget the ordinary landmarks, the many mucous pockets. The treatment ordinarily adopted is similar to a man playing a hose on an open door and hoping in that way to sweep out and cleanse the room. It is the same way when we hope to get the fluid in so as to cleanse the middle ear. We forget all the accessory cavities, the tympanic cellar and attic with its 3 or 4 rooms. These cases must be treated thoroughly or they will run an indefinite course, until the edema subsides and gravity helps the drainage, or until all pockets are destroyed. The medicaments rarely reach the tympanic cavity. It is only by intratympanic syringing that we can hope to cure these cases.

DR. J. F. BARNHILL, Indianapolis—The paper in the main has been one of correct principles. There are, however, a few things that perhaps the essayist, in the short time allotted to him, did not say that he might have mentioned if he had had more time. These cases at the first examination ought to be diagnosticated as perfectly as it lies in our power to do. After the thorough cleansing the Doctor has spoken about has taken place, there ought to be an attempt to determine if there be necrosed bone in any wall of the middle ear, and if any extensive area of this kind be found and definitely determined, it seems to me that the patient ought to be told about it, and if such a procedure as the Doctor has described be undertaken for six or eight weeks, he ought to be given to understand that in all probability a cure will not take place. But if he insists on such treatment, we may go on until he is satisfied that such a procedure will not produce a cure. When we find a dead ossicle or such extensive necrosis, we are absolutely wasting our time by anything short of removing the dead bone. As to the use of boric acid, I believe that boric acid or any powder has but very little and very limited use in otology. In the large majority of the cases that come to us we find perhaps an opening too small to get boric acid or any powder through, and if we can not get the powder into the middle ear itself, we do not get it where it will do good. If the whole of the drum membrane has been swept away and we can thoroughly cleanse the parts and use the boric acid, then, perhaps, we are justified in doing so. In many of these cases the use of any treatment by means of the syringe is, to my mind, as useless and perhaps silly as it would be for the gynecologist to try to cure a suppurating pus-tube by injecting water into the urethra. In very many of these cases, indeed, we find granulations blocking the entire way. The pus may get out, but the injected fluid can never get into the deeper parts in sufficient quantity to do any good. If we stop to analyze the specimens of bones we all have about us, we can see how unwise it is to go on with any procedure short of a radical operation. Understand that I do not advocate radical mastoid work immediately on seeing any case of chronic otitis media unless there is some immediate danger present. If we are able to watch the cases and operate when the danger comes, we are justified in waiting a little. But to wait for six months or a year in the face of a necrotic condition in the middle ear or in the antrum itself is, it seems to me, an otologic folly. I have no doubt Dr. Kuyk cures many cases by his method, just as many of us do, but there are many cases in which we can give the patient at the time of the first examination some knowledge of what he may expect from our treatment.

DR. D. A. KUYK—If, in closing the discussion, you will permit me, I will relate briefly the history of my case and some lessons I learned from it. For fifteen years I received various kinds of treatment for my chronic otorrhea or for the excruciating pain caused by it, but without permanent benefit. Several advocated the mastoid operation, but this I declined. I then began to treat myself, studying my case as each symptom occurred. After experimenting with various methods I begun the dry treatment. After a time it occurred to me to aspirate the suppurating cavity, and this proved beneficial, but occasionally the violent otalgia recurred. I then began the use of compressed air through the eustachian catheter; this produced a feeling of comfort and relief hitherto unknown. I have by this method relieved many violent otalgias. The nitrate of silver solutions were conjointly used for three months, when the discharge and all odor disappeared. The compressed air was continued, and even now I use it once or twice a week, although it has been many years since the otorrhea ceased.

Some one asked if it was possible to remove all the pus from the floor and from the attic. I think it is with the compressed air; if the current used is strong enough the distension of the air into every crack and cranny as it rapidly passes through the ear either forces the pus out or evaporates it and thus removes material that water can not reach and that suction will not coax out.

The use of hydrogen dioxid has even greater disadvantages than has forced syringing. The continuous distension in a practically closed cavity will open those channels that are otherwise closed by the inflamed and thickened membranes, and thus the contents are forced into previously uninfected cavities. I have time and again had patients complain of severe pain following the instillation of hydrogen dioxid, caused, no doubt, by the distension of the inflamed mucous membrane.

As to the use of powders: if the perforation in the drum head is large enough and it is used with judgment no objection can be made to the use of a fine impalpable powder. The powder is lightly blown into the aural canal, the Siegel otoscope is then inserted and the air is forced into instead of exhausted from the ear. A few seconds' continuous pressure will suffice in most cases to force the air through the middle ear down into the eustachian tube and so into the throat.

Copy Your Prescriptions.—At the investigation of a death of supposedly criminal nature . . . the attempt was apparently made to shift the responsibility for the poisoning on the physician, who was asked whether any of his prescriptions contained arsenic or strychnin. A pertinent question was, "Have you the prescription which you wrote out for —— ——?" This will . . . call our attention to the desirability of taking . . . copies of all our prescriptions. Of course the necessity . . . occurs but seldom. When it does occur, however, it is very urgent. Usually the original can be obtained at the drug store. . . . Circumstances may easily be conceived in which it may have been tampered with by interested parties and thus rendered useless for any protective purpose.—*Colo. Med. Jour.*

THE TEETH AS A CAUSE OF PATHOLOGIC CONDITIONS IN THE THROAT, NOSE AND EAR.*

KATE W. BALDWIN, M.D.
PHILADELPHIA.

The little I have to say on this subject I shall put in as few words as possible. The best I can wish is that it may incite others to a more thorough investigation along the same lines.

I feel that it is our duty to call the general practitioner's attention to this subject, as so many of the cases first come under his care. We are all too prone to look on the teeth as so many bones not intimately connected with the body as a whole, which, although useful, can easily be gotten rid of and more or less good substitutes readily obtained. The deciduous teeth are neglected because others are sure to take their places, and how often do we find the six-year molars considered in the same list. The child's face is usually washed at least once a day. In how many cases is the use of the tooth brush unknown to the deciduous teeth and very sparingly used at any time of life. The heat and moisture of the mouth make a fine culture ground for bacteria, and examinations show that many kinds take advantage of the soil so well suited to their use. I wish especially to emphasize the relation between the teeth and the ears, as probably more frequent and more permanent injury results to the organ of hearing than to the nose, throat and accessory sinuses; then, too, we have so much more frequently had our attention called to the connection with sinusitis that we are constantly on the lookout in that direction. I shall cite but one case of empyema of the antrum of Highmore, and I give it because of the unusual symptoms and repeated failures to find the cause. Simple acute tonsillitis and peritonsillitis often result from pressure caused by difficult dentition, especially from the eruption of the wisdom teeth. That these end thus or become suppurative conditions depends on the presence and absence of bacteria in the mouth. Even one carious tooth is always a menace, and we frequently find saprodontia, which is an all too potent cause in the suppurative conditions of the ear, nose and throat. In this connection we ought also to consider the lymphatic glands.

There is no more important point in the specialist's examination than the careful inspection of every tooth erupted and the thoughtful consideration of those about to be; only in the case of the very young infant may we be excused. From habits formed we will usually go over the gums of the toothless infant and be frequently rewarded by finding some unsuspected condition. The fact that a patient is wearing a full upper and lower denture is no excuse. They should be removed and the condition of the gums considered. Only a few months ago I saw a patient who had worn a plate for years and the roots nearly of every tooth were in place, the crowns only having been removed (I was told that the dentist took them off with a chisel). Occasionally a root may be left and the gums completely closed in over it, as in the antrum case I shall mention. A cast of the jaw will quickly show to an experienced dentist the nonabsorption of the alveolus and suggest a left-over root as the probable cause. To have a good dental clinic in connection with every throat, nose and ear clinic is second only to proper instruments and good light. Have the two going simultaneously so that there need be no referring to another day, or even to another hour. If possible, secure a dentist whom you can interest from your own point of view. A ruptured drum membrane and hours of pain will often be saved your patient by the immediate lancing of the gums over an oncoming tooth or by the extraction of a deciduous tooth which is blocking a permanent one, the cleansing of a cavity and the placing of an antiseptic dressing or a filling, the relief of crowding, a little change in a regulating apparatus. To this local treatment always add a brisk cathartic.

At the Polyclinic Hospital, where I have the pleasure of being associated with Dr. Walter J. Freeman, the ear work is separate from the nose and throat, which to me seems undesirable. There is no dental clinic at the hospital, but for years Dr. Freeman has insisted on a careful examination of the teeth in each new case, and has had a graduate in dentistry as an assistant in the clinic. Do not leave the examination entirely to the dentist, but go over every tooth yourself. At another dispensary, where I have throat, nose and ear combined, we have for nearly three years had a dental clinic going on at the same time, and the dentist or undergraduate in medicine has been quite willing to co-operate in any experimental work I have suggested.

In considering the nerve supply, we had best call to mind that a portion of the parotid gland is in close relation with the lower and anterior wall of the external auditory canal and that the anterior wall is also in relation with the condyle of the lower jaw, so that firm closure of the mouth has a tendency to narrow the lumen of the meatus. The posterior and upper walls are formed by parts of the mastoid and squamous portion of the temporal bone. The external auditory meatus derives its nerve supply from branches of the auriculo-temporal, the auricularis magnus and the auricular branch of the vagus. The chief nerve supply to the external surface of the membrana tympani is the auriculo-temporal. According to Shappey, Arnold's nerve (the auricular branch of the vagus) supplies the lower portion of this surface of the membrane, and branches from the tympanic plexus the inner surface. The nerve supply of the tympanum is derived from numerous sources, several nerves entering the tympanic plexus. The nerve supply of the stapedius muscle is derived from a branch of the facial. The nerve supply of the tensor tympani muscle is derived through a branch from the otic ganglion from the motor root of the trifacial or fifth cranial nerve. The chorda tympani nerve, a branch of the facial nerve, may be involved in otitis media, and if so, may lead to abnormalities of the sense of taste on one side of the anterior part of the tongue. Acute otitis media is very frequently associated with the eruption of the teeth, and from reflected irritation produced by carious or even artificial teeth. This complication may be explained by the connection between nerves which supply the teeth and those supplying the tympanum. The great superficial petrosal nerve, which communicates with the tympanic plexus of nerves and through the vidian nerve, joins Meckel's ganglion, which is associated with the superior maxillary nerve. The nerves to the upper teeth are derived from the superior maxillary nerve. The small superficial petrosal nerve communicates with the tympanic plexus of nerves and joins the otic ganglion, which is associated with the inferior maxillary nerve. The inferior dental nerve which supplies the lower teeth is a branch of the inferior maxillary.

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

Interesting reflexes along the auricular branch of the pneumogastric nerve referred to the parts supplied by the parent trunk are, coughing, faintness, nausea, vomiting and sneezing. In sneezing the irritation is reflected, probably along the auriculo-temporal nerve, to the gasserian ganglion or other center of the fifth nerve, and hence referred to the nose through branches of the superior maxillary. This may also account for the unilateral coryza. Earache associated with the upper teeth may be explained in the same manner. Earache associated with the lower teeth and diseases of the tongue are probably due to irritation reflected along the inferior dental nerve and lingual nerve, and referred to the ear through the auriculo-temporal, the other sensory branch of the inferior maxillary nerve.

In going over my records I find so many interesting cases that I can think of giving but a very few selected ones. In adults the third molars or wisdom teeth seem to cause a very large proportion of the trouble with the throat, also much earache.

CASE 1.—22 years old. Both ears had been aching for four days, toothache several weeks. Gums hard and greatly congested over third molars, other teeth in fine condition, gums were freely lanced, a cathartic given. The patient slept quietly all night and had no more trouble.

CASE 2.—Patient four years in getting the four wisdom teeth. During this time had no toothache, but frequent attacks of earache, which were always immediately relieved by a free incision of the gums.

CASE 3.—The eruption of the wisdom teeth extended over six years. About every three months patient had earache, no pain in teeth, earache always relieved by lancing the gums. Earache from impacted third molars, more frequently caused by the upper ones.

CASE 4.—Patient 22 years old. Had facial neuralgia and earache, not relieved by general treatment, referred to dentist. Roots of left superior first molar in position (the tooth was extracted six years previous), inferior second molar, pulp exposed. Roots were extracted, second molar treated and filled. Two weeks later patient reported having been perfectly free from both neuralgia and earache.

CASE 5.—Patient 33 years old. Had had frequent earaches for one year, severe for two days, had prevented sleep. Left external auditory canal and membrana tympani much congested, teeth in good condition, except lower second molar, which had no cavity, but a white chalky appearance. As it gave no trouble the patient refused to go to a dentist. Coal tar products controlled the pain, atropin and a laxative for three days relieved the other symptoms; 11 days later patient returned with practically the same symptoms, which were relieved in four days; 20 days later returned with earache, and the tooth had been growling. She had the tooth extracted and the ear caused no further annoyance.

CASE 6.—Boy 12 years old. For three weeks the left ear and all the upper teeth on that side have been aching, six months previous he had fractured the left central incisor, all the other teeth in good condition. The fractured one was abscissed, the pulp was a putrescent mass. The tooth was treated and all the symptoms relieved.

CASE 7.—Patient complained of deafness and tinnitus and some pain in the ears and that the teeth were in horrible condition. Teeth were in such a condition that the patient was referred to the dentist at once, 16 teeth were extracted and the others treated. Three weeks later reported being all right.

CASE 8.—Child 7 years old. Left ear had been aching for two weeks, no throat or nose trouble of any consequence. The left membrana tympani much congested, one point almost bleeding, teeth in very bad condition, deciduous molars blocking well advanced bicuspids, six-year molars gone to pulp. Teeth were extracted and the ear symptoms quickly cleared up, no pain after extraction.

CASE 9.—Child 1½ years old. Had had pain around left ear for two weeks with some swelling. There was tenderness over the mastoid and congestion of a small hematoma on the posterior wall just in front of the drum, upper and lower molars well advanced, gums greatly congested. The gums were freely lanced and the patient was to return the next day if not better; returned in three days and required no further treatment.

I have recorded seven cases of earache with no evident cause but exposed tooth pulp, all of which yielded promptly to treatment of the teeth; two cases of severe earache during the regulating of cuspid teeth due to tension on the regulating apparatus; many cases of pain in the ear during the filling of teeth, especially molars, this when there was no pain in the teeth themselves; one case of earache and unilateral coryza due to sensitive dentine with no exposure of the nerve; the earache and coryza were almost immediately relieved by filling of tooth and promptly returned on the removal of the filling, this being repeated several times with the same result; twelve cases due to deciduous teeth blocking advancing molars; eleven cases of tinnitus much relieved, if not entirely cured, by treatment of the teeth.

In about 62.5 per cent. of the cases of otitis the teeth were bad, and improvement was much more rapid when the teeth were cared for. A large number of these had passed through the first dentition, so that cases caused by that are not included. In the promiscuous nose and throat cases, where no special ear trouble was complained of at the time, a little more than 50 per cent. had bad teeth.

The only antrum case I wish to report is that of a physician who, when nine years old, had a badly-decayed six-year molar extracted, the roots being left; he was told that they were left and to return if they gave trouble; 19 years later there was pain and a "bone" was removed, followed by a free flow of pus; this was followed by a cessation of symptoms for years, when an attack of grippe in 1890 was followed by empyema of the antrum; this was repeated ten times in eleven years. Each attack was over in a reasonable length of time, but at intervals the patient was much troubled by a very offensive smell, which seemed to come from the nose; for this no local cause was found. During the last attack the antrum was entered under the inferior turbinal, according to Dr. Freeman's method, and the antrum repeatedly washed out, at no time getting much, if any pus, but the horrible odor continued at intervals. For weeks I never got it, when finally, as I was cleaning the tube preparatory to washing, there was an escape of very offensive gas, and it was quite evident that it came from the antrum through the tube; the teeth were again carefully gone over and a cast of the mouth made which showed a lack of absorption of the alveolus. With cutting forceps the alveolus was gone through, and the root extracted, a probe passed freely into the antrum and the opening was enlarged to admit passage of a small syringe and an obturator fitted. Through this opening the antrum was repeatedly washed, but as there was no return of the symptoms, the opening was allowed to close and some weeks later the nasal tube was removed. Up to the present time there has been no return of trouble.

DISCUSSION.

DR. J. C. BECK, Chicago—The Doctor has outlined a number of affections that might follow diseases of the teeth, but the main impression I got from the paper was that there was a great deal of incision of the gum done for the relief of earache. All of us know there is a great deal of earache following disease of the teeth, exposed cavities exposing the nerves and causing pain in the ear when there is nothing pathologic in the ear. But when you speak of incising so many cases for the relief of earache, it is not clear to me that the incision of the gum is going to relieve any suppurative condition in the ear. Beside, incision of the gums has been largely discontinued, because it is not an easy matter to incise the gums, especially of infants, for infection is likely to follow. I would like to have heard more about the condition of the ears and whether suppuration followed in these cases even if the gums were in-

cised. One condition that follows the affection of the teeth is affection of the salivary glands, particularly that condition known as ranula. From caries of the teeth we very frequently find affection of the salivary duct, and then salivary concretions form on top of an infected focus in the glands. One case comes to my mind in which there was reported an abscess of the nose following an affection of a tooth. It was first treated as a simple abscess, incised and drained, but cure did not follow, and finally a secondary operation was done and a cyst was found which was thoroughly eradicated and the case recovered perfectly. This case is reported by Killian.

DR. ROBERT C. MYLES, New York City—This subject is a broad one and has been too much neglected. There are other symptoms, especially those of tracheitis and bronchitis, due to pyorrhea alveolaris, and when the teeth and gums are treated the condition immediately becomes better. I have seen patients who had been treated for months without relief before the proper care was given to the teeth. I must say that dentists do not help us enough in this regard. It has been my experience to refer such cases to the dentist, and the patients returned with the statement that but little could be done for them, and they were usually instructed to use some simple mouth wash. The use of peroxid of hydrogen, especially when followed by an application of alcohol, of which many dentists do not approve, at times I have found most advantageous. It is not practicable to remove all the teeth for pyorrhea alveolaris. As to empyema of the antrum of Highmore, it is very frequently caused by filling a dead tooth, but I do not think dentists should be held responsible for an empyema caused by this procedure. The patients should accept the responsibility. There are bacteria often present beyond and near the root end which the dentist can not get out and the patient must accept the risk when the tooth is filled. The dentist should not be blamed. Many of my patients have been relieved by careful inspection and care of the teeth.

DR. H. M. CRYER, Philadelphia—I would like to answer Dr. Myles especially, for I did not hear all the paper read by Dr. Baldwin. A dentist who would fill a tooth and leave decayed or infectious matter in the tooth or about the root deserves censure, and he would be condemned by the dental profession. We know that the teeth do penetrate nearly or entirely through the floor of the antrum. If those teeth become diseased and the pulp becomes devitalized we may have disease of the antrum, the frontal sinus or the ethmoidal cells, and the dentist who would be responsible for such a result ought to be condemned most thoroughly. If he is unable to get the parts in healthy condition then he should extract the tooth and treat the parts in a surgical manner, even if the disease extends through the antrum into the ethmoidal cells or the frontal sinus.

The essayist spoke of lancing the gums for difficult or retarded eruption of the deciduous teeth. The principal objections against lancing or scarifying the gums is that it produces soreness and cicatricial tissue and often does no good. This fault lies in the operation; the incision must be made deeper than a simple scarification, the object being to liberate the tooth, even if the gum tissue overlying it has to be removed. It is not the pressure of the crown of the tooth against the gum tissue that causes the trouble, it is rather that the ends of the roots that are being formed come in contact with branches of the fifth cranial nerve, when in the lower jaw, with the inferior dental branch. The hardened gum tissue holds the growing roots on the nerve, causing direct pain, and through reflex action will cause various pathologic conditions, such as trouble in the ear, disturbance along the alimentary canal, convulsions, etc. By judicious lancing or removal of gum tissue the child will be relieved, but, of course, if the child has an abscess of the ear it will not be cured by lancing, but will have to be treated surgically as any abscess. The impacted tooth may have been an original factor in causing the abscess.

DR. KATE W. BALDWIN—In answer to the first speaker, I have never had a case of sepsis follow lancing of the gums, and cases of acute otitis have usually been relieved. Of course, if there is a pre-existing suppurative condition it is not cured by treatment of the teeth. But suppurative conditions are relieved much more rapidly if the teeth are put and kept in good condition. When the teeth are in bad condition I am prone to order an antiseptic mouth wash before any work is done on them, which is also to be used after the work is done. Scarifying, I agree with the Doctor, is of no use. You must go through whatever tissue overlies the tooth and give it a chance to advance. I do not mean to say that it will cure a case of suppurative otitis, but it will stop an acute otitis very promptly in many cases, and the suppurative cases will get well more quickly if the teeth are put and kept in good condition.

NOTES ON THE DETECTION AND QUANTITATIVE DETERMINATION OF SUGAR IN URINE.*

A. B. LYONS, M.D.
DETROIT.

The detection and determination of sugar in urine is an old subject, yet one of perennial interest to the practicing physician, and one which, from its difficulty as well as from its importance, invites further research. I propose, in this paper, to treat mainly of some of the newer procedures that have been proposed in this line.

The tests for sugar that have been most used heretofore are reduction tests. They give an indication simply that there is something present which is greedy for oxygen. This is a characteristic which sugar possesses in a high degree, but which it shares with a multitude of organic substances, of which, unfortunately, some are normally present in the urine. If we could find some reagent which would yield oxygen to sugar, but would refuse to part with it to uric acid or creatinin or any other of the long list of organic compounds found constantly or frequently in the urine, we should be able to tell positively after applying the test whether or not sugar was present. As it is, we are to-day not quite certain that sugar in a small proportion is not a normal constituent of the urine.

Several new reduction tests for sugar have been proposed within the past few years. Of these perhaps the most important is methylene blue. When a solution containing glucose is colored with methylene blue, made alkaline with liquor potassæ and heated to boiling, it immediately loses color. If the tube containing the solution is shaken so that the oxygen of the air is brought in contact with the decolorized fluid, unless sugar is still present in large proportion the blue color returns. In case of a solution containing 1 per cent. of glucose, the color may thus be discharged and restored several times in succession before the glucose is completely oxidized.

The test is far more delicate than the familiar indigo carmine test, which differs from this in that the color changes first to lavender, then to red, and finally to an amber or straw color. If only sufficient methylene blue is used to give to the solution a distinct tint, it is possible to detect sugar when the proportion is less than 0.02 per cent. (one-twelfth grain to the fluid ounce). The test, however, can be of little practical value in urine analysis, since normal urine decolorizes the reagent. We may indeed assure ourselves of the absence of any considerable quantity of sugar by using in

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, and approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

the test a single drop, or at most two drops, of the urine. If decoloration does not take place there can not be present as much as two grains of sugar to the fluid ounce. It is possible to make a methylene blue solution of such strength that one cubic centimeter of it will require for decoloration exactly 0.1 milligram of glucose, and so ascertain the maximum proportion of sugar that might be present, but there are better ways to make such an approximate quantitative determination of sugar.

Litmus blue serves as a reduction test for sugar, but is much inferior to indigo carmine, the test being far less delicate.

The ferricyanid of potassium (red prussiate of potash) is an exceedingly sensitive reduction test for glucose. The solution of this salt is of a rich gold yellow color. When made alkaline with liquor potassæ and boiled with a solution of glucose, its color is discharged, the ferricyanid being reduced to ferrocyanid of potassium. If the test be made in a colored solution, or by artificial light, which does not bring out well the yellow color of the reagent, it is still easy to ascertain whether or not this change has taken place, since ferric salts yield a blue precipitate with ferrocyanids, but not with ferricyanids. The solution of ferricyanid must be freshly prepared, and the ferric chlorid must be free from ferrous salt. To make sure of this latter condition, test a little of the ferricyanid solution with a drop or two of the ferric chlorid; the color of the solution will be changed to a deep green, but it will remain transparent, and on diluting will be seen to be perfectly free from a blue precipitate. The test for sugar is to be made, therefore, in the following manner: Put into a test tube 30 minims of a 2 per cent. solution of potassium ferricyanid, add 5 drops of liquor potassæ and a drop or two of the solution suspected to contain glucose. Boil thirty seconds, then add 5 drops of dilute hydrochloric acid or sufficient to render the mixture acid and a drop or two of a 5 per cent. solution of ferric chlorid. A blue precipitate will be thrown down at once if glucose is present. The difficulty with the test is that it is too delicate, i. e., reduction is brought about by substances normally present in the urine, so that the test can not be recommended in urine analysis.

A better reduction test than this is safranin, a red coloring agent. This is used in the form of a solution 1:1000, which is made alkaline with a solution of soda or of potassa and boiled after addition of the solution to be tested for sugar. If sugar is present the red color is changed to a pale amber. By shaking with air the color may be restored, as in the case of methylene blue. The reduction is not as rapidly effected as it is with methylene blue, and the test is not capable of showing such very minute quantities of sugar, but, on the other hand, the constituents of normal urine have comparatively little decolorizing effect on safranin. If 60 minims of the safranin solution are used for the test, with 10 minims of liquor sodæ, 10 minims of a normal urine will not effect decolorization, while the same quantity of a urine containing 0.25 per cent. of sugar will lose its color completely.

In applying heat, be careful not to allow the mixture to boil actively, for oxygen is readily reabsorbed from the air, tending to restore the color. I have not myself made practical use of this test, although I have verified experimentally the general facts stated above, and I incline to think favorably of the test as confirmatory of the indications of other inconclusive tests. The general principle should, however, be laid down that a positive result from a reduction test does not greatly strengthen a conclusion drawn from another reduction test; a negative result in such a case has much greater weight.

After all, we must come back to copper and bismuth as practically the best reduction tests we have. Preference is given by many to the latter on the ground that bismuth is not reduced as often as copper by other constituents of the urine. This advantage is partly compensated by the fact that certain compounds of sulphur part with that element to form with bismuth a black compound which may be mistaken for reduced bismuth. Bismuth is now used oftenest probably in the form of Nylander's reagent, analogous to Fehling's copper solution.

The copper test is, after all, that which is practically most used, and is not likely to be abandoned by those who have learned how to use it. Fehling's solution is much too strong to serve as a delicate test for traces of sugar. It should be diluted with distilled water so as to be of a rather pale-blue color. Sometimes when so diluted it will need to have added to it a little more liquor potassæ—a drop or two only; a large excess of alkali is not desirable. A fluid dram of the diluted reagent is heated to boiling in a test tube and found to stand boiling without reduction. A drop of the urine is then added and the heat maintained 36 to 60 seconds. If much sugar is present the characteristic deposit of cuprous oxid is thrown down. If this does not appear, and if the copper solution remains unchanged in color, three or four drops more of urine are added, and heat applied during another minute. Should the result still be negative, a fresh portion of the test solution should be taken, about 15 minims of the urine added and the whole boiled one minute. If no deposit of cuprous oxid appears, sugar is present only in traces or else there is something in the urine that interferes with the reaction. Possibly there may be an overwhelming amount of sugar, which would, however, be indicated by disappearance of the blue color and development of the characteristic color and odor of Moore's reaction.

It is time to change the tactics. Begin now by boiling a fluid dram of the urine in a test tube, making sure that it is acid. If a precipitate of albumin appear remove this by filtration, add 20 minims of the solution of copper sulphate used for preparing Fehling's solution and again boil. When partially cool add 15 minims of a saturated solution of sodium acetate, which may be prepared extemporaneously by adding to acetic acid sufficient sodium bicarbonate to nearly neutralize it, leaving the reaction, however, distinctly acid towards litmus paper. Filter, and to the filtrate, which is now free from uric acid, xanthin and hypoxanthin, as well as from phosphates, add 20 minims of the alkaline tartrate mixture used for preparing Fehling's solution, and boil one minute. In most cases the presence of sugar will be made evident by the appearance immediately, or on cooling, of the usual deposit of cuprous oxid.

Creatinin, however, is still present and may prove a disturbing factor. It has a reducing action, but has also the property of preventing the immediate deposit of cuprous oxid, and is said to give to the deposit when it does take place, a yellow rather than a red color. In case there is still doubt, therefore, about the presence of sugar, the creatinin must be removed, and this is readily done by the method of G. S. Johnson, as follows:

Add to two fluid ounces of the urine four fluid drams of a saturated aqueous solution of sodium acetate. Boil the mixture five minutes and filter hot; wash the precipitate twice with hot water. Add to filtrate and washings 30 grains of zinc dust and boil 10 minutes to remove excess of mercury. Filter, wash the residue well with water and add to filtrate and washings enough water of ammonia to make exactly four fluid drams. This solution may be used now to determine the quantity of sugar by means of Pavy's copper solution. Since normal urine, even after removal thus of creatinin, possesses some reducing power, the usual deduction of one-half grain to the fluid ounce may be safely made in this determination.

One or two modifications of the copper test deserve mention. In place of Rochelle salt an alkaline citrate may be used with less danger that it may itself cause reduction of copper. Sodium salicylate also may be used, and the test may be made conveniently portable by mixing sodium salicylate with sodium carbonate, and preparing the test solution extemporaneously by putting into a fluid dram of water a little copper sulphate (¼ grain) and adding two grains of the mixture. A deep green solution will result, which on boiling with a few drops of diabetic urine will throw down the characteristic deposit of cuprous oxid.

The copper test is a surprisingly delicate one. By its means the presence of sugar is revealed in absence of disturbing reactions, in two drops of a solution containing one grain to the fluid ounce or in 15 minims of a solution containing 0.02 per cent. When there is uncertainty whether a deposit has been produced or not, the following expedient may be resorted to. After boiling the copper solution with the suspected urine, neutralize as exactly as possible with dilute hydrochloric acid, add a little neutral sodium acetate and a drop or two of a 5 per cent. solution of potassium iodid. A white precipitate of cuprous iodid will be thrown down immediately if there has been any reduction of copper.

An important modification of the method for quantitative determination of sugar by a copper solution is that of Gerrard, known as the cyano-cupric test. Ten c.c. of Fehling's solution are diluted with 40 c.c. of water and heated to boiling. A 5 per cent. solution of potassium cyanid is then added gradually until the blue color is nearly discharged, then drop by drop until the color wholly disappears. Any excess of the cyanid must be avoided. An additional 10 c.c. of Fehling's solution is then added, producing a deep blue solution, which does not now throw down cuprous oxid when boiled with a sugar solution, but suffers reduction with gradual fading of color, as in the case of Pavy's solution.

The determination of sugar is made exactly as with Pavy's solution, the saccharine solution being added from a burette until the color just disappears, the quantity of sugar indicated being the same as if 10 c.c. of the ordinary Fehling's solution had been used. The advantages claimed for this solution are that there is no ammonia to be driven off in boiling, and that oxidation of the solution does not take place so easily as in the case of the ammoniacal solution.

The test for sugar to which I am especially partial is picric acid. It is not new, but the manner in which I use it is of my own devising and is as follows: I prepare in the first place a standard color by dissolving 5 grams of potassium bichromate in 50 c.c. of water, adding 25 c.c. of diluted sulphuric acid, U. S. P., and making up with water to 100 c.c. I put into a test tube exactly 30 minims of the urine together with 15 minims of liquor potassæ and a picric acid reagent tablet and boil one minute. I then add water gradually until the tint of the diluted solution corresponds exactly with that of my standard solution, when test tubes are filled to the depth of 4 cm. with the two fluids and they are viewed from above. I measure the diluted solution, deduct 20 c.c. for "normal sugar," and reckon for each cubic centimeter of the remainder one three-hundredth of 1 per cent. of sugar. In the urine of persons who have taken certain cathartic medicines, such as rhubarb or senna, it may be found that addition of liquor potassæ alone will develop a deep color. In such case mix 30 minims of the urine with 15 minims of liquor potassæ and dilute until the color corresponds as nearly as possible with that of the standard solution, measure the diluted fluid and deduct this measure in addition to the 5 fluid drams above.

There is certainly no quicker way to make an approximate estimation of the quantity of sugar present, and perhaps no way more likely to give results that may be depended on, although it is best to confirm them by an independent method, such as that by fermentation.

The tests hitherto described are indirect, depending on reactions not peculiar to sugar. We have, however, now a reagent which detects sugar by forming with it a definite chemical compound, and which, therefore, gives us greater certainty of our results than any indirect test can. The reagent is phenylhydrazin, the compound formed phenylglucosazone, called for short osazone. It is necessary only to heat the solution suspected to contain sugar with a little of the reagent and some acetic acid to bring about the reaction. The osazone is a yellow substance which crystallizes very readily and in an easily recognized form. The crystals which form in an aqueous solution occur generally in tufts of delicate needles, often nearly spherical or in a sort of dumbbell form, but also frequently in a double sheaf or in groups consisting of two bundles of needles crossing one another at an acute angle, like the letter X. These crystals are almost insoluble in water. They dissolve sparingly in ether, readily in hot alcohol, these solutions depositing them again in crystalline form on evaporation.

To apply the test to diabetic urine the following method, which is essentially that of Neuman, is to be recommended. Place in a test tube 1 fl. dr. (4 c.c.) of the urine, add about 2 gr. (0.12 gm.) of phenylhydrazin hydrochlorid (or two drops of phenylhydrazin itself), add 20 m. (1.3 c.c.) of a reagent prepared by dissolving in 1 fl. oz. (30 c.c.) of acetic acid (40 per cent.) and 60 gr. (4 gm.) of sodium carbonate. Heat the mixture to boiling, pour it into a porcelain capsule and evaporate on a water bath to one-half its volume and allow to cool. If the urine contains as much as one grain of sugar to the fluid ounce a yellow- or rust-colored deposit will form, which will generally show under the microscope crystals of osazone.

I find that the test is more likely to succeed if the urine is first treated in the following manner: To 1 fl. oz. (30 c.c.) of the urine add 1 fl. dr. (8 c.c.) of a 10 per cent. solution of barium chlorid, together with 10 m. (0.65 c.c.) of liquor potassæ. Filter through a double filter, add to the filtrate 10 gr. (0.65 gm.) of sodium carbonate, heat to boiling and filter once more. The filtrate is now free from urates and phosphates and,

therefore, is in a much better condition for the test. To 1 fl. dr. (4 c.c.) of the filtrate add 2 gr. (0.13 gm.) of phenylhydrazin hydrochlorid and 15 m. (1 c.c.) of acetic acid, heat to boiling, transfer to a capsule and evaporate as above.

In case the deposit is not distinctly crystalline, I pour the cold mixture containing it into a test tube, add 30 m. (2 c.c.) of ether, shake together a moment and pour off the ether into a beaker, in which I allow it to evaporate at a very gentle heat. Crystals may or may not form. I expect to find the greater part of the osazone remaining in the aqueous fluid, the ether having removed uncrystallizable impurities. I add to the aqueous fluid an equal volume of alcohol and heat to boiling. When cool, I add 1 fl. dr. (4 c.c.) or more of ether, shake a few moments and allow the ether to separate. This ether I decant into a beaker and evaporate off at a gentle heat, when fine crystals of osazone will almost always be formed, particularly on the sides of the beaker.

Another method of making the test—that of Kowarsky—generally succeeds well, particularly when the urine has been treated as above described with barium chlorid and sodium carbonate. To 1 fl. dr. (4 c.c.) of the urine add 15 m. (1 c.c.) of glacial acetic acid 2 gr. (0.13 gm.) of phenylhydrazin hydrochlorid and 20 or 30 m. (1.5 or 2 c.c.) of a saturated solution of common salt. Boil the mixture three minutes and allow to cool slowly. If sugar is present in the proportion of one grain to the fluid ounce crystals of osazone will separate on cooling, or within an hour or two.

The phenylhydrazin test may fail to detect minute quantities of sugar in the urine, but it is subject to few fallacies. The urine does contain sometimes glycuronic acid which forms with the reagent a crystalline compound closely resembling osazone. The urine of persons who have taken thymol, menthol or eucalyptol contains compounds of glycuronic acid, and, therefore, responds to this test. We are compelled, therefore, after all, in uncertain cases, to fall back on the fermentation test. Now that compressed yeast is to be found in every grocery store there is no difficulty in applying the test.

The fermentation test has always been recognized to be the simplest and most nearly infallible test we have as yet for sugar in the urine. It may fail from the accidental presence in the fluid of some antizymotic agent. Some preservative may even have been added intentionally, but rarely, if ever, without the knowledge of the person who is to make the examination. The method of making the test is familiar to you all. The fact of fermentation, as you know, is evidenced by the escape of carbon dioxid, and by a change in the specific gravity of the urine. Many of you are accustomed to determine the quantity of sugar in a specimen by taking its specific gravity before and after fermentation, and the method is at once simple and trustworthy, if carried out with due care. You are more accustomed, however, to make the test merely as a qualitative one, conducting the fermentation in such a way that any carbon dioxid evolved may be collected.

Some of you have used "saccharometers," which indicate the quantity of sugar present by the volume of gas evolved. The principle of such an instrument is sound. A grain of sugar will yield by fermentation a definite volume of carbon dioxid—a little more than half a fluid ounce measured at 75° F. The fact that has been ignored in all these saccharometers is that carbon dioxid is soluble in water, so that until the fermenting fluid is quite saturated, no gas will be given off. A fluid which contains less than about two grains and a half of sugar to the fluid ounce will, therefore, apparently evolve no gas during fermentation. The gas is there, but it is held in solution.

An obvious expedient to overcome this difficulty would be to saturate the fluid to be fermented with carbon dioxid at the outset. After adding the yeast, a certain quantity of sodium bicarbonate and tartaric acid could be added, the latter in slight excess, and the mixture allowed to stand a few minutes so that any excess of carbon dioxid might escape. A better plan still would be to add to the fluid a quantity of cane sugar, just sufficient to produce in its fermentation gas enough to saturate it completely. The free gas collected under such circumstances would be a substantially accurate measure of the quantity of sugar present.

Another difficulty with most of the saccharometers heretofore used is that the gas as it collects displaces a corresponding quantity of the fermenting fluid, so that their quantitative indications are wholly worthless.

An instrument called the saccharoscope is constructed on scientific principles and enables the physician to determine with a fair degree of accuracy by fermentation the quantity of sugar in a specimen of urine. The instrument has two chambers, in one of which the fermentation is conducted, while in the other the carbon dioxid evolved is collected. The second chamber is filled with water at the beginning of the experiment, but the water is covered with a layer of paraffin oil so that the gas may not be absorbed by it.

A subject I can do no more than touch on at this time is the fallacies that may arise from remedies a patient is using. An exhaustive paper on this subject was presented at the last meeting of the American Pharmaceutical Association by Mr. Frederick T. Gordon, Pharmacist U. S. N. A very large number of the synthetic remedies now in use have a reducing action so that their presence in the urine places in doubt the result of reduction tests for sugar. It is only such remedies, however, as are given in comparatively large doses—a gram or two at least in twenty-four hours—particularly those given in such doses several days in succession, that are liable to be eliminated in the urine in quantities sufficient to lead to the erroneous conclusion that sugar is present. The most important of these are the antipyretic remedies now so frequently prescribed—or used without prescription—acetanilid, antipyrin, phenacetin and salol. To these may be added certain aldehyds or kindred compounds, bromal, chloral, acetal and a number of synthetics more or less frequently prescribed as aspirin, europhen, hydroquinone, urotropin, the latter not often given in quantities sufficient to lead to such fallacies.

The picric acid test is open to fallacies, especially from the use of cathartics containing emodin—senna, rhubarb, buckthorn and cascara sagrada; this has already been pointed out.

The phenylhydrazin test is not affected by the antipyretics or by other reducing agents, but may give a false indication of sugar after the free use of eucalyptol, menthol or thymol. Albumin interferes with this as with most of the sugar tests.

It has happened sometimes that formaldehyd has been added to urine to preserve it without considering that this is not only a powerful reducing agent, but that it interferes with fermentation. Formaldehyd has further the curious property of preventing the precipi-

tation of uric acid by acids, and at the same time of causing precipitation of urea by hydrochloric acid.

The most important of the conclusions reached by Mr. Gordon from his numerous experiments and observations are:

1. The main sources of error in testing urine for sugar will come from the continued administration of many of the synthetics at short intervals in the usual doses; single or widely separated doses of most of these have little effect, as the dilution is too great in the urine.

2. By allowing sufficient time for the drugs to be eliminated from the system, usually only a few hours when not taken long enough to saturate the system, the error their presence in the urine causes can be reduced to a minimum. In cases of doubtful sugar reactions, stop the treatment for at least twenty-four hours before collecting samples of urine.

3. When drugs have been administered for some time, the morning urine will contain the greatest amount of their derivatives.

RECAPITULATION.

To recapitulate briefly the more important points made in this paper:

1. The most convenient preliminary test to apply for sugar in the urine is picric acid, which gives in two minutes a quantitative determination which requires no elaborate apparatus and is generally approximately correct, subject to confirmation by other tests.

2. Of the newer reduction tests, methylene blue is perhaps the only one that will especially interest the physician, and is an exceedingly sensitive test.

3. The copper test yields to none in sensitiveness, and, although more open to fallacies than the bismuth test, need not be abandoned altogether by those who have learned to use it.

4. The phenylhydrazin test is easily made, is more nearly conclusive than any other chemical test, and should always be applied in confirmation of the conclusions drawn from other tests. In inexperienced hands it may fail to reveal sugar when present in a proportion of less than one-half of 1 per cent.

5. When small quantities of sugar are to be determined quantitatively by means of a volumetric copper solution, creatinin should first be removed from the urine by the method of G. Stillingfleet Johnson.

6. By aid of a suitable apparatus, quantitative determination of sugar can be made by fermentation even when the proportion is quite low. The ordinary fermentation saccharometers can not, however, accomplish this, their quantitative results being almost of no value.

I have made no mention of the use of the polariscope, which in its improved form is of great value, particularly where the physician wishes to make daily examinations of the urine of a patient. The instruments are so costly that they seldom form a part of the equipment of a physician's laboratory.

DISCUSSION.

DR. HEINRICH STERN, New York—I think Dr. Lyons laid too much stress on the phenylhydrazin test. In my estimation this is a much overrated test. I have employed the various modifications of the test, those devised by Jaksch, Jolles, Ultzmann and Havelburg. Normal urine treated with phenylhydrazin may occasionally yield crystals which to all appearances are identical to those of phenylglucosazone. The outside appearance of the crystals is no positive proof of their true character. If the phenylhydrazin test is to be depended on, the melting point of the crystals must be determined. Glycuronic and oxalic acids, carbamid, pentoses, etc., combine with phenylhydrazin. The phenylosazone crystals of glycuronic acid or its combinations are exactly analogous to those of phenylglucosazone. The melting point of the glycuronic acid compound is between 114 and 115 C., that of phenylglucosazone in its impure state between 173 and 194, and when pure between 204 and 205 C. The fermentation apparatus exhibited by Dr. Lyons is undoubtedly an improvement over Einhorn's and similar apparatus, as it prevents absorption of carbon dioxid. I am, however, of the opinion that my fermentation apparatus, the urino-glucosometer, possesses advantages over all the other urine fermentation devices. That apparatus is based on the method originally brought forward by Roberts. The apparatus can also be utilized for ascertaining the specific gravity of the urine. The great difference between this and all other fermentation apparatus is that with the aid of the Stern device the amount of urinary glucose may be definitely determined while the other apparatus, at their best, only permit an estimation of the amount of grape-sugar contained in the urine. By placing my apparatus or the specially-designed fermentation tubes into a sandbath or into an incubator in which the temperature is kept at a constant temperature of from 34 to 38 C. complete fermentation of the contents of the tubes may be obtained in from 6 to 8 hours.

DR. A. B. LYONS, Detroit—My paper referred to glycuronic acid and its liability to interfere with the phenylhydrazin test, but I omitted that part in condensing my remarks. I particularly insisted, however, that the phenylhydrazin test must be supported by others, and especially by the fermentation test. There is one other test that I had intended to mention, although I have had no personal experience with it—in fact, I have not been able to procure the reagent, although I sent to a prominent dealer in chemicals in New York for it. The reagent has a polysyllabic name, ortho-nitrophenyl propiolic acid, called for short nitropropiol. It is now to be had under the latter name in the form of tablets for use in urine testing. The presence of glucose is indicated by it by the development of a blue color, which is best made evident by adding a little chloroform, which is colored blue by it. The test is said to be a delicate one. Glycuronic acid also produces the blue color, so that the indication of this test also should be confirmed by fermentation.

THE PRESENT AND FUTURE THERAPY OF ORTHOPEDIC SURGERY.*

NEWTON M. SHAFFER, M.D.
Professor of Orthopedic Surgery in the Cornell University Medical College; Surgeon-in-Chief to the N. Y. State Hospital for Crippled and Deformed Children.
NEW YORK CITY.

The development of orthopedic surgery, as a specialty, has been attended by some incidents and circumstances which I think invite especial comment, for, more perhaps than any other specialty in medicine, its evolution has been influenced by a few men whose personality and whose acknowledged ability, especially in a mechanical way, have contributed to the present successful status. The influence of these pioneers, supplemented by the modern developments of operative surgery, has been to establish in the minds of many some doubt as to what orthopedic surgery really is.

Modern orthopedic surgery in this country may be said to date from the time of Dr. Henry J. Bigelow of Boston, who wrote a "Manual of Orthopedic Surgery," which obtained the Boylston prize for 1844. The essay was on this subject: "In what cases, and to what extent, is the division of muscles, tendons and others parts, proper for the relief of deformity or lameness?" The works of Guerin, Bonnet, Velpau, Phillips, Duval, Little and others were utilized by Bigelow in his essay, and he incorporates strabismus and stammering in his work, with club-foot, torticollis, ankylosis of the knee, flexion of the hip-joint, lateral curvature of the spine, contracted hands and fingers, congenital dislocation, re-

* Read before the American Therapeutic Association, in New York City.

cent and chronic dislocations and locked jaw. This is submitted with a preface, a part of which reads as follows: "It is believed that the general intention of the committee will be fulfilled by an attempt to cover the ground now occupied by orthopedic surgery."

It will be noticed that no mention is made in this essay of Pott's disease of the spine, hip-joint disease or of any other of the deformities due to chronic or progressive diseases of the articulations, all of which may result in deformity or lameness. Nor was it until 1855 that these diseases and deformities of the joints attracted especial attention. At that time Dr. Henry G. Davis introduced his famous traction splint for the treatment of hip-joint disease and his equally efficient antero-posterior support for Pott's disease of the spine, and the pathologic conditions underlying these diseases began to be appreciated if they were not fully understood, although Dr. Davis distinctly stated that they were tuberculous. Davis' apparatus was quickly adopted, amplified and improved by his contemporaries, and Bauer, Taylor, Sayre and Knight soon after, by their strong personalities and marked abilities, established what has since become known as "The American School of Orthopedic Surgery."

Thus it is that the subcutaneous tenotomy of Stromeyer (1830), supplemented by Little of London, Detmold of New York, and others in the same field, and the later efforts and successes of the pioneer American orthopedic surgeons, made a legitimate school of orthopedic surgery which has been augmented and amplified by numerous eminent men, whose work has been greatly to the credit of medicine and surgery.

In the meantime an important advance in the treatment of deformities occurred with the introduction of osteotomy and osteoclasis and the plaster-of-paris bandage. The treatment of knock-knee, bow-leg and other osseous deformities were thus brought under the classification of acute fractures; in short, under the care of the general surgeon, who became independent of the orthopedic surgeon and the use of specially constructed apparatus in the treatment of these conditions. The application of the gypsum bandage was taught in the medical colleges as much so as other conventional splints, and the general surgeon found himself equipped to do much work that formerly fell to the orthopedic surgeon. Orthopedic surgery, therefore, found itself confronted by a serious question, a question I tried to solve in an address[1] before the orthopedic section of the Berlin International Congress in 1890, in which I said: "There would be no true orthopedic surgery to-day if mechanico-therapeutics had not been studied long and patiently by a comparatively small body of intelligent surgeons." This statement is just as true to-day as it was twelve years ago, and it revives the question as to what really constitutes orthopedic surgery, and what should be its future status as a specialty, especially from a therapeutic standpoint.

For the purpose of discussing the future therapy of orthopedic surgery let us dismiss from our minds the various non-inflammatory long-bone deformities, such as knock-knee, bow-leg, etc., which however much the orthopedist may claim them, will be operated on and successfully treated by the general surgeon. They are conditions with which, after a certain age, the general surgeon can easily cope and their future therapy is not so liable to undergo marked changes as that for other deformities to be considered later. A considerable number of these long-bone deformities, however, will always be treated by mechanical means, and the operative measures for these deformities are not gaining in popularity.

In an address[2] before the Board of Trustees of the New York Orthopedic Dispensary and Hospital, delivered in 1897, I made the following assertion: "It will be along the line of conservatism that orthopedic surgery will be developed, not on the lines of operative surgery."

Let us study this aspect of the subject and see where it leads. As a fundamental principle let us quote as general propositions the following:[2]

1. "The treatment of chronic deformities would be emasculated if mechanical treatment was omitted. Indeed, under these circumstances there would be only operative surgery left."

2. "The operative part of orthopedic surgery becomes the simple but necessary adjunct of the mechanical work."

These simple propositions underly, I think, the present and future therapy of orthopedic surgery.

No one who is familiar with the present mechanical aids of the orthopedic surgeon can avoid the conclusion that they are still in their infancy. The apparatus now in use will be thought very inefficient by the orthopedic surgeon fifty or one hundred years hence. So also with many of our present methods. They will all be revised, amplified and improved or perhaps discarded for others, based on a clearer conception of the various conditions involved. The therapy of the orthopedic surgery of the present day represents an undeveloped, but necessary, specialty. It represents, especially from a mechanical standpoint, inspiration, rather than the result of study and research. It represents the clinician rather than the pathologist. It represents intuition rather than inductive reasoning. Davis struck an important principle when he imitated Nature and made an apparatus do what the human hand, guided by the human intellect, accomplished. Taylor, a born mechanician, would sit down, scissors in hand, and cut out a pasteboard pattern of an apparatus for club-foot. Sayre could apply with his deft hands a gypsum splint in a way that I have never seen equaled. Knight would intuitively devise apparatus for a given deformity and make a creditable drawing of it at a moment's notice. In stating these characteristics of these honored men I have no thought of detracting from their other eminent and recognized abilities. Still, I never knew any of these pioneers in orthopedic surgery to work out a problem in the application of artificial mechanics to a human deformity on what might be called a scientific basis. It seems foreign to their nature, and perhaps to their training, to imagine any one of these men defining a deformity with a scientific formula, such, for instance, as is used by the ophthalmologists of the present day. But this scientific method must come before orthopedic surgery can claim a safe position among the specialties of surgery, and this method will be used to describe certain deformities, not only for permanent record, but to meet the intelligent comprehension of the profession.

No one doubts the potent influence of these men in founding a distinct branch of surgical inquiry; and no one can take exception to their abilities or to their well-earned renown. They have given us a point of common interest around which we may all gather, and they have pointed out the way to grand results. But the problems they have left unsolved only stimulate inves-

2. The Operative Side of Orthopedic Surgery. N. Y. Medical Record, Dec. 18, 1897.

tigation and study among their humble followers, and it seems almost useless to say that these investigations and studies will not be so much with the knife, chisel and saw, as in the almost unexplored fields of mechanical therapy, and in pathologic exploration.

The future therapy of orthopedic surgery must answer, among many other unsolved problems, the following, viz.: a more scientific way to make traction in hip-joint disease; the successful relief and cure of lateral curvature of the spine; the prevention of deformity in Pott's disease, especially in the dreaded respiratory region; the prevention of deformity in hip-joint disease; the radical and permanent cure of congenital dislocation of the hip; the relief of many of the urgent deformities of infantile spinal and cerebral paralysis; the permanent and speedy cure of flat-foot and allied conditions, and the relief and cure of many deformities dependent on tuberculosis, now only exceptionally successfully treated. The future development of orthopedic surgery opens up a wide field that scarcely invades operative surgery. It invites the physiologist, the pathologist, the surgeon and the mechanician alike, and the successful orthopedic surgeon of the future must combine all these.

At present the foundations are laid—that is all. The same principles which have guided the minds which have made the Brooklyn bridge an everyday conventional affair, will guide the minds which conquer the unsolved problems of orthopedic surgery. No one man will do it. A syndicate of far-apart thinkers, earnestly working for the same end, perhaps by diverse methods and from totally different standpoints, will ultimately formulate means of relief and cure which now seem unattainable.

Looking at the therapy of orthopedic surgery to-day, one must be impressed with the tendency which exists to cultivate the surgical at the expense of the mechanical. The eagerness of the medical student to witness the bloody and difficult operations in the amphitheater, while he neglects the equally necessary mechanical details of the orthopedic department of college work, is reflected in the profession at large. This applies to some who are best known as orthopedic surgeons. They will operate with skill and interest in a given case of deformity not, perhaps, really requiring operative work, only, when the operation is completed, to turn their patient over to an uneducated mechanic in steel for much of the subsequent treatment. On the other hand, it is not uncommon to find a complicated apparatus, useful enough in the hands of a skilled surgeon, but utterly useless in the hands of the inexperienced, pictured in the numerous catalogues of instrument-making firms, which are so freely circulated among the profession. Since the introduction of the plaster-of-paris bandage, the profession have been less dependent on this class of men, but only because the use of plaster of paris has been taught in the medical colleges. But to the skilled orthopedic surgeon the plaster-of-paris bandage in many instances will always be a "ready-made clothing" affair, for he will prefer, in nearly every case, to adjust and adapt an apparatus, based on scientific principles, which meets the indications and which can be adjusted even in minor particulars to meet the requirements of the condition under treatment. In short, he will make his apparatus a veritable prescription which can be modified by his own hands, and he will discard, as far as he can, all fixed forms of apparatus, of which the gypsum splint is a typical example. Those who thus make themselves personally responsible for the mechanical therapy of their patients are perhaps not numerous in the profession to-day. But those who have followed this method have probably saved orthopedic surgery as a distinct specialty from being absorbed by general surgery.

In order to bring the future therapy of orthopedic surgery up to a proper standpoint the medical colleges throughout the world should be equipped with a completely appointed mechanical laboratory where the students will come in contact with the various deforming diseases of childhood, and be taught in a practical way the mechanics of the human frame and the application of artificial mechanical means to relieve and cure deformity, especially of the parts involved in locomotion. Writing on this subject in 1898, I say:[3] "The next progressive step in the surgical care of deformities will be to establish a mechanical laboratory where the practical use of apparatus in the treatment of deformities may be intelligently taught in all our medical colleges."

This, it seems to me, is the most important step in the future therapy of orthopedic surgery. The student having been made familiar with the important first principles of mechanico-therapy, and educated in the essential details of the application of the ordinary forms of apparatus, the importance of mechanical therapy will be recognized, and much that is now left to the imagination of the student will be clearly defined. And this means that orthopedic surgeons who accept appointments in college work should be masters of a subject that is now quite neglected.

My plea, therefore, is for an advanced therapy for orthopedic surgery which will place it where it will be a true specialty, quite apart from general surgery, where those who practice it will bring to bear on its many interesting problems a close study of its pathologic bearings, a clearer conception of its surgical necessities and a recognition of the extreme value of a close study and a more scientific development of its mechanical side.

We have no school of applied mechanics in our medical colleges. We can demonstrate the surgical (operative) measures. We can illustrate symptoms and diagnosis, in the clinics and in the sectional teaching, but we can not give the practical instruction which is necessary in mechanico-therapy without a well-equipped laboratory; in short, a shop supplied with power and tools and controlled by a master at the head of it all.

When I read my essay on "What Is Orthopedic Surgery" before the Berlin Medical Congress in 1890, I attempted to define orthopedic surgery as follows:

"Orthopedic surgery is that department of surgery which includes the prevention, the mechanical treatment, and the operative treatment of chronic or progressive deformities, for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary."

I can see no reason for changing this definition. Any surgeon fully mastering the conditions laid down in this definition will find his hands fully occupied and his heart and brain interestingly engaged in a work that will meet with ample reward, and which needs no other approval than that of his own conscience.

3. On the Care of Crippled and Deformed Children. N. Y. Medical Journal, July 9, 1898.

Amyloform as a Specific Against Coryza.—The personal and clinical experience of H. Lepa, as detailed in *Med. Blätter*, No. 5, establishes that the harmless powder, amyloform, will arrest a cold in the head in its early stages and relieve it at any stage. He combines it with equal parts of rice starch and uses it freely as a snuff every hour or oftener.

PRIMARY CARCINOMA OF THE NASAL CHAMBERS.

WM. EDGAR DARNALL, A.B., M.D.
Physician to the Atlantic City Hospital; The Mercer House for Invalid Women; Late Physician to St. Michael's Children's Hospital.
ATLANTIC CITY, N. J.

It is not common to find malignant disease attacking the nasal chamber. When it does, however, it is found to be sarcoma more frequently that carcinoma. Kyle and Bosworth both point out the infrequency of these conditions in the nose. The latter, in 1889, succeeded in collecting 41 cases of sarcoma and 30 cases of carcinoma of the nasal cavities. Gibb,[1] after a careful search of the literature, has been able to add 70 cases of sarcoma and 48 of carcinoma, making a total of 111 cases of sarcoma and 78 cases of carcinoma. In a special practice of ten years he has only seen one case of primary carcinoma of the nasal chambers, but he considers sarcoma not nearly so rare as statistics would seem to indicate.

The case of carcinoma I wish to add to this list occurred in a German woman of 69 years of age, who had always been a hard worker. There is no special interest attached to it except the short term of its duration; but since this disease so rarely attacks the nasal chambers this case is worthy of record, if only to make the statistics more complete, and it brings the number now up to 79 cases.

The patient was not seen early enough to determine the exact position at which the trouble started, but the appearances indicated a beginning on the middle turbinate. The favorite site, however, of primary carcinoma of the nose, it is stated, seems to be in the proximity of the ethmoid and sphenoid cells, high up in the nasal cavity. When the case was first seen there was a history of occasional epistaxis and the usual stenosis, causing a stoppage of the nose, and it was thought to be due to an ordinary mucous polypus. The patient passed out of the writer's hands and consulted a local surgeon, who attempted to remove the growth. He succeeded in getting a portion of it away and in producing a hemorrhage that was with difficulty controlled. The patient later went to a surgeon in Philadelphia, who made two unsuccessful attempts to remove all adventitious tissue, and sent her home with the advice that she had better not have it further interfered with. When she came into my hands again, some time after this, there was a distinct swelling on the right side of the nose. There were lancinating pains through the face and head and an irritating characteristic discharge from the nose. The nostril was filled with the growth. The antrum and superior maxilla soon succumbed to its advance and its appearance on the face through the skin made the nature of the growth unmistakable. The cervical lymphatics were involved, and after a while the roof of the mouth as well as the upper pharynx showed the progress of the disease. By this time exophthalmos was present to such an extent that the right eye was crowded entirely out of its orbit, producing the characteristic frog-face appearance and being attended by intense suffering.

The progress and duration of carcinoma of the nose varies with the character of the growth. The medullary and adenocarcinomata are said to be the least malignant and of the longest duration. Neudorfer reports a case which had existed for eleven years. Heurteaux reports a case of tubular epithelioma which had lasted fourteen years, and a case of adenocarcinoma is reported by Hopkins which lasted twelve years. All other varieties are of rapid growth. The shortest duration noted by Gibb are the cases of Pepper and Shakespeare, in which death took place within seven months. The writer's case, which was seen a short time after the symptoms were first complained of, in November, died the following June, making a duration of seven months. I have seen no case reported of shorter duration than this. Bosworth's case lasted nine months. The average duration is stated at about a year and a half, and the case here reported is therefore one of unusually rapid progress. No doubt the rapidity of its progress was hastened by the surgical interference which, failing to completely remove the diseased tissue, only encouraged its further growth.

The prognosis in all cases of carcinoma of the nasal cavity is decidedly unfavorable. In the light of our present knowledge there is but one variety which offers any ground for a favorable prognosis, and that is the so-called cylindroma of Billroth. If the site is favorable for complete removal, Gibb and others advise removal, but unless one is reasonably sure of being able to remove completely all diseased tissue it is better not to attempt it, for the interference, instead of accomplishing anything, only accelerates the disease and produces a fatal termination more quickly.

VACATION NOTES.

G. FRANK LYDSTON, M.D.
Professor of Genito-Urinary Surgery, Medical Department, University of Illinois; Surgeon to St. Mary's Hospital.
CHICAGO.

(Continued from p. 246.)

3. AUCKLAND, NEW ZEALAND.

For the benefit of any of my friends who may chance to take a trip to New Zealand and Australia I will suggest the wisdom of remembering the fact that they may expect weather the diametric opposite of that which they leave at home. Leaving San Francisco in the early autumn and finding myself three weeks later in the beginning of the New Zealand spring impressed this on me most emphatically. The weather became raw and cold three days before arriving at Auckland. Soon after this change of weather we arrived at the 180th meridian and I had the, to me, novel experience of losing a day out of my life. Saturday night was succeeded by Monday morning. Sunday was lost. This was sad, but was mitigated by several things. In the first place I didn't know it was Sunday that I had lost until I discovered it quite by accident. I had lost all track of time. Then, too, it would have been a rainy Sunday, anyhow, and I couldn't have gone out in my automobile. Best of all, the volunteer pastor of our peregrinating flock was cheated out of his usual sermon. He was an English preacher, with atrophy of the "H" center, nasal obstruction and a raucous voice. His creed was not evident to my inexperienced ear, but it was strictly orthodox, and had so much brimstone and fire in it that, by contrasting their present with their future state, the seasick ones found themselves well. If one could only select the day which he loses—I have had several that I never would have missed.

Auckland, the principal city of New Zealand, is a most charming place. The harbor is landlocked, commodious and as beautiful as could be desired. I was told that the harbor of Sydney was much more beautiful, and was perforce compelled to believe that it must be so, as it has the reputation of being the most beautiful in the world; but the fact remains that Auckland harbor seemed ideal.

The scenic surroundings of Auckland are indeed wonderful. It is not my province to regale the readers of THE JOURNAL with descriptions of scenery, but I can not refrain from mentioning the scenic panorama unfolded to the tourist's gaze from the summit of Mount Eden—most appropriately named. The city of Auckland itself is especially beautiful as viewed from the mountain top. The harbor lies before one in all its loveliness, while stretching away in all directions as far as the eye can reach is a scenic display of picturesque buildings, well-kept small farms and gardens which it would be difficult to equal. In the distance one can see several of the wonderful inlets of the sea, or sounds, for which the New Zealand coast is so famous. Not the least of Auckland's attractions is its extreme cleanliness. Another favorable item is the cheapness of its hotels. Good hotel living is to be had at rates which stagger the American. Strangely, "tipping" is almost unknown.

The Auckland Museum is well worth seeing. It contains a collection of Maori implements, weapons, boats, houses and wonderful carvings, which form a most valuable contribution to ethnology, and is a pathetic monument to a noble and unfortunate race, which, through the rapacity and cruelty of the white man, has become almost extinct. It is not fitting that I should describe the various interesting relics of the Maoris. I will merely mention a couple of mummified heads prepared by them which are very remarkable for the preservation of form and features and the ligneous character imparted to the tissues by the method of embalming. One of these heads bears the tattoo marks which embellished it during life. The other has been engraved as if it were hard wood with various fantastic designs simulating Maori tattooing.

One of New Zealand's wonders is the Kea, a large, handsome parrot. This bird, originally herbivorous, has become carnivorous. He is a specialist in his way, and destroys sheep in a most peculiar manner. He alights on his victim's back, tears open the lumbar region and devours the perinephritic fat. He is not averse to other fatty portions of the body, but, when sheep are plenty, he absolutely ignores all portions of the sheep save the perirenal fat. Thousands of dollars worth of sheep are killed annually by these birds.

A feature of New Zealand which looks quite singular to an American physician is the large proportion of insane in the islands. The proportion of male insane to the total population is 1 in 165. Inclusive of Maoris it is 1 to 281. The female insane are in a proportion of 1 to 367. The grand total is 1 to 300, exclusive of Maoris. Inclusive of Maoris it is 1 to 316. This is a frightful showing, and hard to explain, in view of the apparently favorable conditions prevailing in that beautiful country.

New Zealand is especially boastful of its scenic health resorts, and with reason. The lake country, of which the Rotorua district is the center, teems, with medicinal springs—both hot and cold—boiling lakes and phenomenal geysers. It is growing to be a very popular resort for invalids of all descriptions. Like all spas, those of New Zealand are accredited with hundreds of wonderful cures "given up by the doctors." The invalid who is not cured is consoled by the wonderful scenery, so what would you? A peculiar fact regarding New Zealand is the steady, marked decrease in the number of marriages. The country does not lack marriageable young men and women, and all conditions are favorable to matrimony, yet the institution is unpopular. The moral status of the islands is nevertheless high and the proportion of illegitimate children low. The latter-day New Zealand family is small. These conditions are really a source of uneasiness to the thinking residents. There is no explanation of a social character for the abnormal conditions mentioned. One can not avoid the suspicion that some general neuropathic cause underlies both the phenomenal prevalence of insanity and the paucity of marriages.

New Zealand certainly does not suffer from a lack of hospitals. The annual expenditure for hospitals is considerably over $500,000 aside from private subscriptions and endowments; this sum for a population of 900,000 whites and 40,000 Maoris is by no means insignificant.

There are a number of private and several government sanatoria at the various spas, in the North Island especially. The government owns all the hot and mineral springs, and at Rotorua provides a resident medical officer, whose services are free to the patrons of this famous resort. One great advantage of government ownership and supervision is the nominal fees charged for living and baths at the various springs.

Auckland has but one hospital worthy of the name, the Auckland Hospital. This is under the control and support of the municipality. It is located most favorably on a beautiful hill just out of the thickly settled part of the city, in the midst of a large acreage of as fine land as ever lay out of doors. The spacious grounds are well kept and beautified by superior landscape gardening. The main hospital building was erected in 1875, and looks more than its age. It needs the painter's services badly, but its architecture is not unhandsome. The hospital, with its charming environments, makes a very attractive picture. The interior appointments of the main building are, of course, not strictly modern, yet there are many hospitals in our American cities which might well pattern after that of Auckland. A number of fine pavilions have been added from time to time, mainly by private charity. The nurses' home, in particular, is worthy of notice, and a special pavilion for gynecology shows the progressiveness of the institution. These are all fine buildings, located at a sensible distance from the main hospital. There are also special pavilions for contagious diseases, the hospital being a general one and taking all classes of cases. The only cases of plague which Auckland has had—two in number—were cared for here. The hospital has an average attendance of 205 patients, so the annual total is very large. The accident and emergency service is excellent. Over 1,000 surgical operations were performed last year. Operations for appendicitis were very numerous. Dr. Collins, the superintendent, operated on two cases the afternoon before my visit to the hospital. He was particular to inform me that he only opened and drained in cases with a large walled off pus cavity, using gauze drainage. I asked him whether the hospital surgeons leaned toward radicalism or not, and he replied: "We operate as soon as we get the case, save under special and exceptional conditions." How Americanism does spread, to be sure! Dr. Collins modestly asserted that they were somewhat behind the times over there—unavoidably so. A few moments' conversation with him, however, showed that self-laudation was not his strong point. Good work, up-to-date work, is being done in Auckland, and Dr. Collins is doing his share of it.

Apropos of the American influence in surgery abroad, sundry remarks made by Dr. Collins were very pleasing. Speaking of vaginal hysterectomy he said: "We used to use the permanent forcipressure for the vessels, but we now use Pryor's operation of splitting the uterus in halves. It is a fine operation." Referring to procedentia, he said: "Here is our favorite operation." Down came a text-book; it was opened at a full-page illustration, and the doctor pointed his finger at—my friend, E. C. Dudley's, operation. Hurrah for Chicago! He wound up by saying he was going over to see our own Kelly to get some points. Verily, the world is moving United Statesward. The gynecologic service at the Auckland is very large and the cases varied. The vaginal operation of hysterectomy is frequent enough to delight any of its partisans.

The Auckland Hospital has an operating room built three or four years ago, which was as good as the best at the time. It is to be remodeled and refurnished, however, on "American lines." The out-patient department of the Auckland is very large, 11,000 patients having been treated last year.

There is no midwifery at the Auckland, such cases are sent to a small, rather inferior maternity hospital, an independent institution. Prostatic surgery is at the forefront in New Zealand. Suprapubic prostatectomy is the favorite operation, but the Bottini is being tried in occasional cases. As usual, I said a good word for the perineal method in suitable cases.

An excellent training school is one of the features of this excellent institution. Its usefulness is greatly enhanced by the splendid building which one of Auckland's wealthy citizens built for it—the pavilion already alluded to. The number of nurses is 57.

SATURDAY, JANUARY 31, 1903.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

We print in this issue a communication and an official announcement, each of which is of importance at the present time. The communication is a letter from the President of the American Medical Association to a New York physician and bears directly on the present condition of affairs in that state, and indirectly on membership in the American Medical Association throughout the United States.

As stated by Dr. Billings, a committee was appointed by each of the New York state bodies for the purpose of considering the possibility of uniting the two into one organization. For a time it seemed that the efforts of the committees would result satisfactorily and a union be consummated. Then matters came to a standstill and the prospect for a settlement was as far off as ever. At this point President Billings, hoping against hope, asked for a conference with the two committees. The result of the conference is to be found in his communication. In brief, it appears that the proposition of the committee representing the New York State Medical Association was at first accepted, but later refused by the committee representing the society, viz., that the Medical Society of the State of New York should be the name of the reorganized body, that the general plan of organization of the New York State Medical Association should be adopted, that the New York State Medical Association should cease to exist, and that a committee representing both should go before the legislature for a new charter.

While at the recent conference objections were made by the society committee to certain business and legal obstacles, the code, without doubt, was the one thing that blocked the efforts for union. Considering that a revised code had already been introduced and is in the hands of a committee to report at New Orleans, that an informal agreement relative to certain changes in the code was made at Saratoga between men representing the society, the association and the American Medical Association, and that affiliated societies are not now required to formally adopt the code, it does seem that the committee representing the society was not governed in its action by a too great amount of liberality.

The official notice regarding membership needs no further comment or explanation than is contained in the circular letter signed by the Secretary and the preamble, with its decisions, signed by the President and the Secretary. The medical profession is being organized on a definite and systematic principle, a principle which is the basis of all organizations, viz., that membership in the lower is necessary for membership in the higher body. This principle has always been the one governing membership in the American Medical Association, although it has not heretofore been enforced.

ANOTHER STEP IN THE RISE OF SURGICAL PHYSIOLOGY.

Physiology, and by necessity experimental physiology, is by its nature the basis of restrictive and constructive surgery in so far as this is scientific and other than empirical. Physicians and surgeons are beginning at last to realize this principle adequately, although, of course, it has been always obvious to anyone who consciously defines to himself physiology as the science of normal organic function. Surgeons seem recently to have acted on this hopeful idea more than have physicians proper—and they have reaped corresponding benefits. One has heard for many years what one is sometimes tempted to term a surfeit of pathologic anatomy, whereas at present the signs certainly suggest physiology as the systematic science likely to add most to medicine during the succeeding years.

The latest contribution of experimental physiology to surgery and medicine is by Crile[1] of Cleveland. By more than two hundred experiments on dogs (conducted without pain) Crile has been privileged to explain more satisfactorily, at least, the physiology of collapse and shock, and to show how these may be prevented or overcome in fact, as formerly they have been in theory. Collapse, less dangerous than shock, appears to be a condition of very low systemic blood-pressure, whatever be the cause, whether hemorrhage, poisoning of the vasomotor center, serous effusion, extreme peripheral stimulation, or what not. Shock, on the other hand, seems to depend on low pressure of blood in the tissues when this depression is due to exhaustion of the vasomotor center, supposedly in the medulla oblongata. Of the three neurons in the vasomotor path, the uppermost is probably the one which is exhausted in shock. In this condition the ordinary cardiac stimulants, such as strychnin, digitalin, alcohol, are proven either useless or positively harmful, for these stimulate the heart, and mere heart action, however vigorous, can seldom overcome the low blood-pressure in arteries no longer kept in tone by the exhausted center. Alcohol, it is found, does not produce even the momentary rise which strychnin and digitalin afford. The infusion of normal saline is beneficial for a very brief time, raising the pressure, but the injected liquid in a few minutes finds its way into the intestine; it is in collapse, then, and especially that from hemorrhage, that the injection of salt solution is of so great use.

1. See prellminary note in THE JOURNAL, Jan. 24, p. 244.

In shock the blood-pressure must not only be raised, but it must be kept raised until the agencies causing the shock have abated and the organism has begun to regain its equilibrium. Since the vasomotor center in shock is out of function, this effect must be brought about in the periphery by agencies acting directly on the toneless arterioles. One way, logically, to bring this about would be to make universal pressure on the vessels, and accordingly Dr. Crile devised and had constructed a suit of rubber consisting of a double air-tight fabric which could be drawn over the legs and abdomen and over the arms and then inflated till it exerted the required pressure. This raises mechanically the blood-pressure all over the body and prevents the especially dangerous cerebral anemia.

But more notable even than this in its effects is adrenalin chlorid, one of the newest of the organic enzymic products, and certainly that at present with the largest promise of usefulness. This enzyme, as is its physiologic function, acts directly on the muscular tissue of the heart and arteries, causing these by this means to regain their normal tonus, thus restoring the pressure necessary for the tissues to carry on their usual metabolism. It is recommended that adrenalin be very slowly injected into a vein, as from a pipette or burette, thus allowing a very long continuance of the injection. This is necessary, for adrenalin is quickly oxidized and its enzymic properties lost when it is put into the circulation.

Such a procedure undoubtedly makes it practicable to perform safely much longer and more depressing surgical operations than formerly were proper. Its chief advantage comes, however, from the means it so readily affords of tiding over a bad case of shock of whatever origin, until natural conditions of the organism begin to be spontaneously restored. We shall await the development of the practical applications of this investigation, which seems likely to have an important bearing on future surgery.

AN ANTIDOTAL SERUM FOR INTOXICATION WITH MORPHIN.

The tolerance in some instances to drugs whose administration is long continued is a well-recognized clinical fact, the explanation for which may perhaps be found in the modern views on the subject of immunity. It seems not impossible that there may be produced in the body under such circumstances antisubstances capable of acting in the same way as the antitoxins of the infectious diseases. It has been observed that while in cases of acute intoxication with morphin, for instance, the greater part of the poison is eliminated with the feces, in cases of chronic intoxication with the same substance very little of the poison is eliminated with the excreta. From this observation it is concluded that under the latter conditions new factors have been created for the destruction of the morphin in the body.

With the object of determining whether it is possible first to develop in animals a relative degree of immunity to the effects of morphin and then with the serum obtained from such animals to develop a similar immunity in other animals, Leo Hirschlaff[1] undertook an experimental study. Rabbits were first employed for the preparation of a curative serum because they exhibit great resistance to alkaloids in general and to morphin in particular. A daily injection was given, and two kinds of serum were prepared, one from animals immediately on the close of their immunizing treatment and the other from animals four weeks after conclusion of the treatment. While control animals succumbed to lethal doses of morphin, other animals previously treated with the protective serum did not succumb to an equivalent dose. As the results in rabbits exhibited marked variability, mice were later used in the observations. Here again it was found that animals previously treated with the curative serum were secure against lethal doses of morphin, while animals treated merely with normal serum or not all previously treated succumbed. The best results were obtained with the serum from animals that had received as much as 10 grains of morphin at a dose, and there was little difference whether the serum was obtained immediately on completion of the protective treatment or after an interval of four weeks. It thus seemed demonstrated that by the treatment for some time of animals with progressively increasing doses of morphin protective substances are generated in the blood that are capable when injected into other animals of protecting these from acute intoxication with a lethal dose of the same drug.

Analogous results have been obtained on a smaller scale by other observers. The question remained open, however, whether these observations on lower animals were applicable also to man. An opportunity presented itself for the employment of the curative serum in a case of opium poisoning in a human being, and fortunately the result justified an affirmative decision. The serum was employed also in several cases of insanity in which morphin had been given for a long time and attempts at withdrawal had always been attended with unpleasant results. In these withdrawal was now effected without any undesirable manifestations. If the future of this serum proves as bright as its seeming possibilities indicate, it will be indeed a valuable addition to therapy.

A MEDICAL LIBRARY JOURNAL.

The first number of the *Medical Library and Historical Journal* has come to hand. This quarterly is published in Brooklyn, under the editorship of Drs. Albert Tracy Huntington and John Smart Browne, and contains a considerable amount of good reading in the way of original articles, on matters of medical, historical and bibliographical interest and the transactions of the Association of Medical Librarians, together with editorials, book notices, etc. It contains an Index Medicus of medical books published in the last quarter of

1. See p. 343 of this issue for abstract (162) of the original.

1902, which it claims is as nearly correct as possible, though the editors admit that perhaps one or two local publications might not have come to their attention.

KOCH'S NEW TYPHOID PROPHYLAXIS.

The *British Medical Journal* of January 10 editorially notices a recent address on typhoid fever by Professor Koch, in which he takes views in regard to the prophylaxis of the disease that are of interest coming from him and for being somewhat different in their intent and consequences with those usually held. Instead of using special precautions to protect the drinking water, he prefers to attack the disease in the foci where it exists, and holds that the surest method of prevention is in the isolation of the patient and disinfection of clothes and excreta. In this way he has experimented at Treves so successfully that he has been able to stamp out the disease completely in several villages which had been notorious for its frequency. Our readers will see that this is somewhat along the line on which Koch fights malaria. He attacks the disorder in the individual, and prevents infection by preventing infection breeders. It will be a boon to tax-payers if we can consider the question of water supply a secondary matter and make the problems of sewage disposal and water supply, with their expensive installments, needless. But this, we think, will hardly be the case. Koch's method, however good, will not substitute itself to the satisfaction of sanitarians. In fact, they will be slower to accept such opinions than were the tuberculosis specialists to accept his opinion as to the transmissibility of bovine and human tuberculosis. It will be an excellent idea, however, for all practitioners to follow out his policy of thorough isolation and complete and absolute disinfection of all excreta in such a way as to make it impossible for infection to escape into the sewage and thus directly or indirectly contaminate the water supply. The method is a comparatively easy one. It only requires close and conscientious attention and thorough instruction and insurance that such instruction is carried out. We would advise individual physicians to follow out Koch's ideas. It will cost but little and will perhaps only require a little more careful attention than has hitherto been given to isolation and disinfection.

THE DIETETIC VALUE OF OYSTERS.

The oyster is popularly looked on as a palatable, easily digestible and nutritious article of food. That there is some danger from its consumption has of late been shown in a number of instances in which typhoid fever has been acquired from the ingestion of oysters that have been grown or fattened in waters contaminated by discharges from patients suffering from that disease. It has recently been suggested that lemon juice is inimical to the vitality of the typhoid bacillus, and the suggestion appears to be sustained by the results of bacteriologic investigation. Accordingly, the recommendation has been made that the danger of infection with typhoid fever through the eating of oysters can be greatly lessened, if not entirely eliminated, by the addition of lemon juice. For the purpose of determining the nutritive value of the oyster the *Lancet*[1] recently had made in its own laboratory a study of the chemical composition of native oysters, which yielded interesting and instructive results; and there is no reason to believe that the findings would be essentially different in the case of other varieties. It is pointed out that although the actual amount of nutritive material in a raw oyster is small, it comprises all classes of food substances, namely, proteid, carbohydrate, fat and certain mineral salts, and these are present in a peculiarly assimilable form. Generally speaking, the raw mollusc consists four-fifths of water, the remainder being constituted almost entirely of organic matter. Of the latter about 45 per cent. consists of proteid, an equal proportion of non-nitrogenous matters and the remainder of glycogen and fat. Mineral matters are present in about 2 per cent., including sodium chlorid, soluble phosphates, calcium phosphate, magnesium phosphate and copper in the form of oxid. The oysters were found to be readily soluble in cold water, diluted gin and Chablis (a delicately acid wine), but not in stout. The oyster is rendered tough and indigestible by boiling. The liquor contained in the oyster shell consists principally of water and sodium chlorid and almost no organic matter, and accordingly it possesses no special nutritive value.

WHAT ONE COUNTY IS DOING.

It has been said, and with some truth, that medical men are not business men. It is certainly true that in the past our medical societies and medical organizations have not been business bodies in any sense of the term, but purely scientific and educational. While this, as far as it goes, is noble and idealistic, nevertheless it is recognized that a little more business, a little more medical statesmanship and a little more attention to the materialistic side would not be out of place, and ought not to detract from the scientific and educational, but rather add thereto. In the present plan of organization the business principle, while not pushed to the front, is recognized. In this connection we can not resist the temptation to call attention to what one society has already done. The Ramsey County (Minn.) Medical Society, the county in which St. Paul is situated, four years ago began the formation of a library and at the same time founded in connection with it the *St. Paul Medical Journal*. The library has been gradually built up and at the present time has over four thousand volumes, all catalogued and shelved in a commodious hall, which is also the meeting room for the society. The use of the hall is given, rent free, by the management of the building, which is devoted to offices almost entirely occupied by physicians. The journal has been a financial success from the beginning and puts considerable money into the treasury of the society each year, beside being the means of placing on the shelves of the library practically all the better books that are published, several hundred volumes annually. Further, all the exchanges are placed in the library, so that practically every important journal of the county is in the reading room of the society. The society also has a well-equipped laboratory for chemical and bacteriologic work, one of the important prod-

1. The London Lancet, Jan. 3, 1903, p. 71.

ucts of which is sterilized catgut, sold at a profit. The laboratory gives to the members of the society a place in which to work, and many avail themselves of the privilege. The society takes great pride in its journal, which is one of the best medical monthlies in the country, and which is edited on a high ethical standard. Each enterprise is separate and distinct from the other, each making a full report to the society at the end of the fiscal year. One of the members says, "Our dream is to lay by a little money every year for the establishment of a fund which will ultimately enable us to buy a piece of ground, and later to own our own home." There is no doubt that the society has been built up and strengthened very materially by these enterprises. It has now over 150 active members and the officers expect very shortly to have in the society every reputable practitioner in the county. What the Ramsey County Medical Society has done can be done by other societies similarly situated throughout the country.

Medical News.

COLORADO.

December Deaths.—The total number of deaths for the month was 843, equivalent to an annual death rate of 17.12 per 1,000. Typhoid fever caused 44 deaths; diphtheria, 19, and scarlet fever, 4.

Communicable Diseases.—During December the following cases of communicable diseases were reported to the State Board of Health: Typhoid fever, 242; diphtheria, 178; scarlet fever, 157, and smallpox, 126.

Personal.—Dr. James B. Sanford, Castle Rock, was elected to the House of Representatives in November last, and on January 7 was elected speaker of the house.——Dr. William A. Cundy, Denver, has sold his practice and has located in Pasadena, Cal.

Dedication of Guggenheim Pavilion.—The Guggenheim pavilion at the National Jewish Hospital, Denver, was formally dedicated January 25. This pavilion has been erected at a cost of $35,000. In the three years the hospital has been in existence, $225,000 has been contributed for its support.

Allege Diploma is Bogus.—Dr. Gottfried Leo Hagenburger, formerly of Helena, Mont., charged with filing a bogus diploma with the State Board of Medical Examiners of Colorado, has been granted a continuance. This individual had similar trouble in Montana several months ago, it being then alleged that he had never been in attendance at the medical school of the University of Kiel, and that his diploma, purporting to be issued by that institution, was a forgery.

ILLINOIS.

State Board of Health.—At the annual meeting in Springfield, January 13, Dr. James C. Sullivan, Cairo, was elected treasurer.

Smallpox Closes Schools.—It is announced that the public schools in the vicinity of Alto Pass have been closed on account of smallpox.

Hospital Gets Lots.—By the will of the late Chancellor L. Jenks three lots in Evanston are devised to the Evanston Hospital Association.

Staff for St. Mary's Hospital, Quincy.—The following staff has been appointed for St. Mary's Hospital, Quincy: Surgeons—Drs. Otis Johnston, John D. Justice and William H. Baker; gynecologists—Drs. Henry Hart, John K. Reticker and Otto F. Wellenreiter; pathologists—Drs. John D. Justice and John A. Koch; oculists and aurists—Drs. Henry M. Harrison and Franklin T. Brennan; physicians—Drs. Grant Irwin and John A. Koch, and anesthetist, Dr. Thomas Knox.

Chicago.

Physician Robbed.—On January 22, Dr. Michael T. Naughton was held up and his money and gold watch were taken from him.

Hospital Fete Nets Thousands.—The "Fête of All Nations," held January 24 to 26, in behalf of St. Luke's Hospital, was successful beyond all ideas of its managers. More than $20,000 was realized for the hospital.

To Guard Against Contagion.—The prevalence of contagious diseases has led to the passage of an order by the City Council for an assistant city bacteriologist and a medical inspector for the municipal lodging-house, while an appropriation of $3,000 for an isolation hospital for the Parental School was also voted.

The Deaths of the Week.—The commissioner of health, in the bulletin for last week, congratulates the city on a decrease in the death rate. There was a drop of 9.7 per cent. from the average weekly death rate of the previous five weeks and of 12 per cent. from the rate of the week before. The report says:

> The total deaths reported during the week were 551, an annual rate of 15.23 per 1,000 of population, as compared with 626 and an annual rate of 17.31 per 1,000 during the previous week. The rate, however, is still excessive, being nearly 10 per cent. higher than the normal for the season of the year.

Pneumonia Outnumbers Tuberculosis.—The registrar of vital statistics, in his report for the week ended January 24, discusses the pneumonia-tuberculosis death ratio as follows:

> For twelve successive weeks the deaths from pneumonia have largely outnumbered those from consumption, although the disparity was not so great last week as in the previous weeks. During this period 6,579 deaths from all causes have been recorded, of which total 630—or a little more than 9.5 per cent.—were from pneumonia. These two causes account for more than one-quarter (26.12 per cent.) of all deaths during the three months, and of these there were 42 per cent. more from pneumonia than from the so-called "Great White Plague."

INDIANA.

Conditional Benevolence.—A citizen of Connersville is said to have offered $1,000 in cash and two building lots to the city, with a provision that each church has a director and $9,000 additional be raised for a city hospital.

St. Anthony's Staff Feasts.—A banquet was given by the sisters, at St. Anthony's Hospital, Terre Haute, to the medical staff, January 5. Dr. Frederick W. Shaley was re-elected president of the staff, and Dr. Charles Wyeth, secretary-treasurer.

Sues on Account of Fall.—Dr. James H. F. Prentiss, Indianapolis, has brought suit against James and Mary Proctor, for $10,000 damages for personal injuries alleged to have been received by him in a fall down a flight of stairs in a building owned by the defendants.

Personal.—Dr. Hugo M. Lash has succeeded Dr. Frederick C. Heath as a member of the Indianapolis Health Board.——Dr. Alfred N. Towles, Irvington, has been appointed physician at the Indianapolis City Dispensary, vice Dr. Frank Kennedy, who has become house-physician at the Julietta Asylum.

Physicians Protest Against Pesthouse Location.—Several prominent physicians of Indianapolis, headed by Dr. William N. Wishard, have written letters to the local board of health protesting against the erection of the isolation hospital on land immediately adjoining the City Hospital, on the ground that the close proximity of the pesthouse will endanger the lives of patients in the hospital.

IOWA.

New Hospital Ready.—Patients were transferred from St. Bernard's Hospital to the new Mercy Hospital, Council Bluffs, January 19. The old building will be devoted to the care of nervous patients.

Prepare Premedical Courses.—Several Iowa colleges, including Grinnell, Cornell and Augustana, are arranging premedical courses in connection with the State University whereby graduates may be admitted to sophomore standing in the medical department.

Cornerstone Laid.—The cornerstone of the pathologic laboratory of the College of Medicine of the State University, Iowa City, was laid, January 15, with appropriate ceremonies. Dr. John C. Shrader, one of the founders and ex-dean of the college, officiated and delivered the address.

Personal.—Dr. Frances M. Powell, Glenwood, has been reappointed superintendent of the Institution for Feeble-minded Children, for a sixth term of four years.——Dr. Andrew W. McClure, Mount Pleasant, has resigned from the board of insanity commissioners, and has been succeeded by Dr. Otto A. Geeseka.——Dr. John G. Mueller, city physician and health officer of Iowa City for four years, has resigned.——Dr. Anson R. Brackett, Charles City, is critically ill with septicemia.

MARYLAND.

Smallpox in Kent County.—Dr. Frank Messick, Still Pond, has been appointed health officer of Kent County, vice Dr. Urie, resigned. There are no new cases of smallpox reported at Chestertown in that county since the discovery of the case in the colored girl from Wilmington, Delaware, January 20. A quarantine of the child and of all who came in contact with her has been established, and all residents of the town have been vaccinated. A pest-house has also been made ready for emergencies.

Baltimore.

Baltimore General Dispensary.—At the annual meeting of the Baltimore General Dispensary, January 15, Drs. Henry M. Baxley, Edmund A. Munoz and James C. Holdsworth were elected attending physicians for the year.

St. Joseph's Hospital Dispensary reports 12,471 cases treated during the year, distributed as follows: Surgical, 5,240; medical, 4,718; children, 627; skin, 215; eye and ear, 479; gynecological, 563, and nose and throat, 629; 16,849 prescriptions were filled.

Hospital Annual Meeting.—At the annual meeting of the board of governors of the Presbyterian Eye, Ear and Throat Charity Hospital, the medical executive committee, which has managed the medical affairs of the institution for the last four years, consisting of Drs. Herbert Harlan, Hiram Woods and Frances M. Chisolm, was reappointed for this year, with Dr. Herbert Harlan as surgeon-in-chief.

Disease and Death.—The death rate continues high, 249 deaths being reported last week, being 22.02 per 1,000 for whites and 31.07 for colored. Among causes of death affections of the respiratory organs led, with 31 from pneumonia, 17 from broncho-pneumonia, 2 from acute and 5 from chronic bronchitis. Tuberculosis of the lungs caused 26 deaths and measles 11; 311 new cases of measles were reported.

Silver Nitrate in Septicemia.—The physicians of the Union Protestant Infirmary are experimenting with nitrate of silver in cases of blood poisoning with alleged success in several cases. The formula given is 1 c.c. of a 10 per cent. solution of nitrate of silver to 1,000 c.c. of sterilized water. Of this 400 to 1,000 c.c. are injected into the vein at the elbow. Dr. J. Whitridge Williams is said to prefer the normal salt solution.

National Medico-Historical Society.—The proposal for a national society devoted to the history of medicine, made in the new *Medical Library and Historical Journal*, just issued, is meeting with much favor, and it is probable that a number of gentlemen of literary tastes and connected with the Johns Hopkins Hospital Historical Club will take part in its foundation. It is a little singular that at this time the interest in the history of medicine should be greater in this country than in the older countries of Europe. It is only within the last two years, for example, that such societies have been founded in France and Germany.

Methyl Alcohol Blindness.—The trial of the suits against a Baltimore drug firm for blindness due to the use of methyl or wood alcohol instead of grain alcohol, in the manufacture of essence of Jamaica ginger, began in the Superior Court, January 22. The first suit for $30,000 was brought by Dr. George A. Brehm of Rolandville, who claims to have been made entirely blind two days after drinking three bottles of the essence on July 27, 1898. He bought the preparation from a storekeeper on Elliott's Island, Dorchester County, where he then lived. Dr. Reid Hunt and Mr. Henry P. Hynson, druggist and ophthalmologist, testified.

NEW JERSEY.

Physician Gives Laboratory.—Dr. William B. Graves, East Orange, has presented a well-equipped bacteriologic and pathologic laboratory to the Orange Memorial Hospital, to be known as the Graves Laboratory.

Personal.—Dr. Charles C. Hendrick, Jersey City, county medical health inspector, has been removed from office.——Dr. Edwin J. G. Valentine, Jersey City Heights, has been made a member of the Hudson County Health Board.

John Carnrick Dead.—In the recent death of Mr. John Carnrick, Jersey City, the ranks of the pioneer drug trade of the United States have lost an able leader. He was among the first to bring out proprietary preparations and to manufacture drugs for physicians. His life was largely devoted to scientific research in his chosen field of pharmacy. He was 65 years of age, and had been a student of pharmacy for more than forty years.

NEW YORK.

Smallpox at Fort Slocum.—Smallpox has broken out among the 400 soldiers at Fort Slocum, just outside of the Borough of the Bronx.

Scarlet Fever at Dunkirk.—Dr. George E. Ellis, recently appointed health officer of Dunkirk, has been obliged to close one of the public schools because of an epidemic of scarlet fever.

Voluntary Patients for State Insane Hospitals.—The State Commission in Lunacy recommends the extension of the system of voluntary patients for the reason that in certain private asylums these patients receive inadequate care and treatment.

Registration of Trained Nurses.—It is said that a bill will be introduced into the legislature, providing for the supervision of all nurses' training schools by the State Board of Regents. According to the provisions of the bill, the required course of training must be at least two years in an incorporated general hospital or a training school connected with such hospital.

No Appropriation for State Tuberculosis Hospital.—It has come to light that through an error in the records of the last legislature, either accidental or intentional, the bill calling for a reappropriation of $50,000 for the State Hospital for Tuberculosis failed of passage in the assembly. Senator Davis, who introduced the bill, and others, insist that the bill did pass the assembly. The fact that the appropriation had not been made was not discovered until the trustees attempted to make the first payment on the site selected for the hospital.

New York City.

Fire in Seton Hospital.—A fire was discovered in the basement of the Seton Hospital, January 18, which was extinguished with small loss without the help of the fire department.

Bacteriologist and Laboratory Assistant Wanted.—The Municipal Civil Service Commission announces that open competitive examinations for the position of bacteriologist (fourth grade) and laboratory assistant (first grade) will be held February 3 and 6 respectively. Applications should be made to the secretary, 61 Elm Street, New York City.

The Health Department and Malaria.—The health department has employed a corps of inspectors to go through the various boroughs and plot down on maps all sunken plots and excavations in which water may remain and become stagnant. With the aid of the department of street cleaning, these holes will be drained and filled in. The sanitary inspectors are directed to pay special attention to rain barrels and pools in back yards. Finally the health commissioner has sent a circular letter to all physicians in the city, calling their attention to resolutions recently adopted by the board of health. These require all public institutions, hospitals, homes and asylums to report all cases of malarial fever coming under their observation, with information whether the attack is a primary one or a relapse, and where the disease was apparently contracted. All physicians are requested to furnish similar information with regard to their malarial patients, and are encouraged to do so by the offer of examining blood specimens for them for the malarial plasmodium. The circular closes with the statement that acute and chronic ophthalmia (trachoma) and whooping cough are on the list of contagious diseases, which physicians are required to report.

Buffalo.

Sudden Deaths from Natural Causes.—It has been suggested that the health department investigate deaths from natural causes without medical attendance. Heretofore these investigations have been carried on by the medical examiners. Dr. Greene, the health commissioner, will cause these investigations of sudden death from natural causes to be made by the district physicians.

Grand Jury Condemns County Hospital.—The grand jury of the Supreme Court of Erie County has made its final report and has this to say concerning the Erie County Hospital:

> The grand jury desires to say the hospital is entirely inadequate to the present needs of the county, and in view of the rapid growth of the city, the county will need much more room in the very near future for the hospital.
>
> In the opinion of the grand jury the county should furnish increased facilities for the hospital and we would recommend that the county purchase a farm outside the city limits for the poor of the county and that the present buildings now used for the almshouse be devoted to the use of the hospital.
>
> The operating room of the hospital is not what it should be to meet the sanitary requirements of the present time. It should be remodeled to equal the present sanitary demands of physicians and surgeons.

PENNSYLVANIA.

Railroad Yards Quarantined.—The railroad yards at North Bessemer are quarantined because of a smallpox epidemic in Plum Township, Allegheny County.

Appropriation to Suppress Smallpox.—The state senate has passed a resolution providing for the appropriation of $15,000 to aid the State Board of Health in suppressing smallpox.

A Healthy City.—Secretary Lee of the State Board of Health has notified the authorities of Williamsport that reports show that city to be the healthiest in the state, and the fourth healthiest in the United States.

Eddyites Fight for Charter.—Argument was recently made before the Supreme Court of the state regarding the granting of a charter to the First Church of Christ, Scientist, of Philadelphia. District Attorney Weaver contended that the so-called "divine healing" is a menace to the community, against law and public policy; that the appellants come into court with two contrary doctrines, namely, saying that there is no such thing as disease, and yet they educate "healers" to cure sickness. He further argued that the sect does nothing to prevent the spread of disease, and does not regard the means of prevention in epidemics such as is recognized by boards of health. Attorney Weaver had been requested by the board of judges to defend the decision of President Judge Arnold of Common Pleas Court, refusing a charter to the church.

Philadelphia.

Typhoid and Other Deaths.—For the week ended January 24, 35 deaths from typhoid fever occurred; there were 294 new cases reported, a decrease of 29 cases, as compared with the preceding week. Deaths from all causes numbered 615, a higher death-rate than for any week in the last two years.

Avoid Consumptives' Houses.—January 21 Dr. Lawrence Flick lectured on tuberculosis before the women's clubs. He warned especially against moving into houses previously occupied by consumptives, where disinfection had not been done, and also against the employment of consumptive servants, and emphasized the efficieney of cleanliness as a preventive measure.

New Maternity Donated.—At the recent annual meeting of the board of trustees of the Presbyterian Hospital announcement was made of a gift of $30,000 by an unknown donor, for the erection of a new maternity house. The work of construction will be begun in the spring. The women of the Presbyterian churches in Philadelphia have started a fund for its endowment. The report of the superintendent showed that 2,500 persons were treated in the hospital within the past year and 6,000 at the dispensaries.

Vaccination Against Tuberculosis.—Dr. Leonard Pearson, dean of the Veterinary Department of the University of Pennsylvania, is reported to have discovered a method of vaccination whereby cattle may be made immune to tuberculosis. In a recent experiment, four healthy cows were taken; two were vaccinated, and later all four were inoculated with tubercle bacilli. When killed, the two which had been vaccinated showed no signs of tubercular infection, but the others had marked evidence of the disease.

A Medical Carnegie Library.—Largely through the efforts of Dr. S. Weir Mitchell, Andrew Carnegie has made a gift of $50,000 to the College of Physicians of Philadelphia, on condition that the society raise a like amount. About $18,000 has already been raised, and efforts are being made which will doubtless secure the requisite sum. Much of the gift will probably be used to enlarge and improve the college building, especially the capacity for library purposes. The medical library, in value and number of volumes, is second only to the Surgeon-General's library, Washington.

May Repeal Law.—The state legislature is showing every disposition to remove the obstacle in the way of Philadelphia accepting the Henry Phipps gift of $1,000,000 or more for the establishment of an institute for the study and treatment of tuberculosis. A bill to repeal the act of 1899, which forbids the erection of a hospital in the crowded part of a city, has passed the senate, and a committee of the house has announced its decision to report the bill with a favorable recommendation. Temporary quarters have already been leased for the institute, and it is hoped that it may be opened in about two weeks.

GENERAL.

Ecuador Quarantines San Francisco.—All ports of Ecuador have been closed to all vessels from San Francisco which left that port January 20 or later, because of fear of the plague. All ports are also closed to all plague-infected Mexican ports.

Publishing House Branch Secures Editor.—The firm of W. B. Saunders & Co. have established a branch office in the "Flatiron Building," New York. Dr. Reed B. Granger, who has been the managing editor of the *New York Medical Journal* for many years, has resigned that position to take up the management of the Saunders new office. The apartments on the seventeenth floor give a fine view of the city and will be a pleasant place for visiting physicians to call. Dr. Granger's wide acquaintance and his executive ability will serve him well in his new position.

Army Surgeons' Examinations.—Candidates for appointment in the Medical Corps of the Army will be examined by the Army Medical Board in Washington, April 20, and each Monday thereafter so long as is necessary. Full information as to method of application, nature and scope of examination, etc., will be furnished by the Surgeon-General's office on request of those interested. Applicants from civil life are restricted in age to 29 years, and hospital training or professional experience in private practice is expected of all candidates. There are at present thirty-five vacancies to be filled.

The Plague Unchecked in Mexico.—One-third of the 15,000 inhabitants of Mazatlan have left that city and every community within a large radius, including the border states and territories of the U. S., is apprehensive lest plague be spread thereby. The appearance of the disease is reported at several cities in Mexico. A wholesale poisoning of rats in Mazatlan has failed to be effective and the government has ordered the valuable shipyard to be burned to destroy infection. The adobe houses are being burned and razed to destroy the rats. One hundred and thirty thousand dollars has been received by the charity commission for relief work. A supply of the Yersin serum has been sent for and is eagerly awaited in the hope of relief by inoculation. There have been more than 150 deaths at Mazatlan. The mortality average is 33 per cent. The origin of the disease is discussed in the papers of the Southwest and the infection is laid at the door of San Francisco. In the absence of any present proof, it is said to be the most probable solution that ships carried infected rats or persons from San Francisco to Mazatlan. That city is isolated by mountains from the rest of Mexico, no railroad enters it and almost all of its communication with the world is by steamers from San Francisco and Panama. Chinese go there from San Francisco and there is no Chinese quarter in Mazatlan, but they scatter throughout the city, which is devoid of sewerage or sanitary provisions. Panama has no plague and has now refused its harbor to a ship from San Francisco. The other theory as to the infection of Mazatlan is that it came by ships from the Orient. This is said to be possible, although such ships rarely stop at Mazatlan.

CANADA.

Personal.—Dr. W. H. Drummond, Montreal, was entertained by the Calumet Club of New York, January 17, and subsequently dined with President Roosevelt at Washington, D. C.

Vital Statistics in Ottawa.—In 1902 there were recorded in the capital of the Dominion 1,638 births, 571 marriages and 1,190 deaths. The natural increase in population was 448. The city clerk reports a decided improvement in the registering of births.

Smallpox Outbreak on Indian Reserve.—Smallpox is rampant among the Indians on the Tyendenaga Reserve, near Belleville, Ontario, thirteen cases having been reported during the past few days. The reserve has been strictly quarantined and patrolled, while the patients have been carefully isolated.

The Vancouver (B. C.) Hospital reports for December 51 patients admitted and 51 discharged cured; 4 died, and there remained in the hospital, December 31, 46 patients, 36 males and 10 females. The Canadian Pacific Railway has subscribed $200 per annum to the maintenance fund. The total subscriptions received in 1902 amounted to $18,000. Dr. McGuigan was appointed one of the visiting directors for January.

Laval Students Banquet.—The medical students of the University of Laval, Montreal, held their annual dinner January 17. Sir William Hingston replied to the toast to "Our Professors," pointing out the necessity of medical practitioners specially qualifying themselves to meet emergencies, instancing the cases of King Edward and President McKinley, when the eyes of the whole world were on the medical profession.

Mortuary Statistics in St. John.—The deaths in St. John, N. B., for 1902, numbered 706. Infectious diseases for the year

were as follows: Diphtheria, 75 cases, with 12 deaths; scarlet fever, 108 cases, 1 death; typhoid fever, 21 cases, 7 deaths; measles, 9 cases, no deaths; smallpox, 6 cases, no deaths, Tuberculosis of the lungs amounted to 82 cases. Of the total number who died, 555 belonged to Canada; 149 foreign; 2 not stated.

Victoria's (B.C.) Health.—The general health of the city of Victoria during the past twelve months has been good, there being at no time a tendency to an outbreak or epidemic of contagious or infectious diseases. In all there were reported 83 cases of diphtheria, with three deaths and 48 cases of scarlet fever, with no mortality. There was only one case of smallpox, and prompt measures controlled any chance of an outbreak. The system of boxdrains is said to be the cause of the large proportion of cases of diphtheria. It is worthy of note that the death rate of 12.33 for 1901 has decreased to 10.09 for 1902.

Canadian Quarantine Laws.—Representatives of the Montreal steamship companies waited on the Minister of Agriculture at Ottawa, January 21, to ask for changes in the quarantine laws. They assert that there is an undue detention of vessels and passengers on the St. Lawrence, and that there is far more promptitude shown in releasing vessels and passengers at New York. The minister pointed out that the regulations on the St. Lawrence and at New York are identical. He promised to ascertain how the quarantine law is administered at New York, and that, if improvements could be applied to the Canadian system without endangering the public health, it would be done.

FOREIGN.

Prize for Schleich.—The Würzburg University has awarded the Rinecker prize to the Berlin surgeon and professor K. L. Schleich, as a token of appreciation of his method of local infiltration anesthesia.

Koch on a Mission to Africa.—Robert Koch, accompanied by Neufeld and Kleine, all of the Berlin Institute for Infectious Diseases, have left for a protracted stay at Rhodesia to study the cattle plagues.

Fatal London Streets.—Of 90 deaths in London from other than natural causes last week 1 was from homicide, 9 suicide and 80 from accidents or carelessness. About 4,000 persons, in round numbers, are killed each year in the streets. This number exceeds the total number of soldiers slain in battle in the Boer war.

Insane Women Die in Fire.—The annex of the Colney Hatch Insane Asylum, six miles north of London, burned January 27 before daylight, and 54 women inmates died. The buildings are called fire-traps, being built of wood and without sufficient exits. Heroic work by the attendants prevented a larger loss. There were 600 women patients in the entire asylum.

Bavaria and Compulsory Sanitation.—A petition from the "Nature healers" recently presented to the Bavarian parliament asked for the suppression of all medical forcible interference on human beings for purposes of diagnosis, treatment or immunization. It was referred to a committee which presented a unanimously favorable report. The local medical journal comments that the action of the committee is a sad sign of the times, but one whose significance should not be depreciated.

Physicians Refuse Unscientific Association.—The twenty-eight physicians under contract with a certain large sick benefit society at Gera, Germany, all resigned when a "Nature healer" was appointed a member of the medical staff on the same terms as the rest. The Leipsic Medical Union has resolved to sustain them in their action and has issued an appeal stating how the Gera colleagues are battling for the honor of the profession, and warning all medical men to refrain from serving the said benefit society under any conditions whatever, until the matter is satisfactorily arranged.

Esmarch's eightieth birthday was celebrated with much ceremony January 9, with congratulations from scientific societies and members of the profession in all countries. His name is connected not only with military and other surgery, but with the organization of Samaritaner or first aid relief system in city and country. His pamphlet on "First Aid in Emergencies" has been translated into twenty-five languages. Esmarch married the aunt of the present emperor of Germany, and has been profusely decorated with honors and titles. He is the son of a physician at Toenning, and has been privat docent and professor of surgery at Kiel since 1859. He bears his eighty years lightly and is in vigorous health.

LONDON LETTER.

Tetanus Deaths in Antiplague Inoculation in India.

An unfortunate, and so far unexplained, mishap in the antiplague inoculation in the Punjab has occurred. The anticipated supply of serum was not forthcoming and a change was made in the method of its preparation. Notwithstanding this, 120,000 people were voluntarily inoculated during the month of October. It soon became apparent that the fluid supplied was not free from contamination, and some of it had to be rejected. A few cases of death occurred, apparently from its use. Then at Mulkowal 17 persons were found suffering from tetanus and died. The government will liberally compensate the families. All inoculation was then stopped. The original method will be resumed and the old serum is now being prepared. The plague mortality throughout India continues to increase. For the week ending December 6 12,400 deaths were recorded, as against 12,039 for the previous week, and 8,878 in the corresponding week of last year.

The Health of London.

Dr. S. F. Murphy, medical officer of the London County Council, has just presented his annual report on the health of London for the year 1901, in the form of a somewhat bulky volume. The estimated population of the "administrative county of London" in the middle of 1901 was roughly four and a half millions. The steady decrease in the English birth rate in recent years, which has been already referred to in THE JOURNAL, is once more exemplified. The birth rate was 29 per 1,000—the lowest ever recorded. The death rate was 17.1, which is lower than that of the other great towns—Liverpool, Birmingham, Manchester, etc. The death-rate of children under the age of one year was at the rate of 148 per 1,000 births—a lower mortality again than that of the other great towns. The annual zymotic death rate was 2.22 per 1,000. The deaths from smallpox numbered 229, being at the rate of .051 per 1,000. The number of cases of smallpox was 1,700, or a case rate of .375 per 1,000 persons living. In spite of the existence of the epidemic of smallpox in the second half of the year the death rate from that disease was lower than in Paris, Brussels, St. Petersburg, Vienna and New York in the period 1891-1900, and in Paris and New York in 1901. The number of deaths from cancer was 4,203, the corrected annual average for the preceding 10 years was 3,843—showing the tendency to increase of this dire malady.

Tuberculosis of the Esophagus.

At the Pathological Society Dr. F. C. Shrubsall and Dr. W. T. Mullings showed a specimen of this condition, which is so rare that no case has ever been described in the British Isles. The specimen was from a man aged 50, who was admitted to hospital with hydropneumothorax. Dysphagia came on suddenly a few days before death, and was relieved only by swallowing a solution of cocain. There was no evidence of pharyngeal ulceration, but early tuberculosis of the larynx was discovered. At the necropsy tuberculosis of the lungs, intestines, right testicle, trachea and bronchi were found. The bronchial and mediastinal glands showed no macroscopic evidence of tuberculosis. In the middle portion of the esophagus was extensive ulceration over a length of 3½ in., the individual ulcers being oval, with their long axis in the long axis of the tube. Below this were a few scattered ulcers. Microscopically typical tubercles with giant cells and tubercle bacilli were demonstrated.

Outbreak of Smallpox in Liverpool.

Until last year Liverpool had enjoyed a long respite from smallpox. Now the disease is rife in the city. During the last week of 1902 there were 74 fresh cases, and on December 31 26 additional cases were notified, making upward of 206 cases. Fifty fresh cases have been reported within the last week. Revaccination is being strongly urged by the medical officer of health. Unfortunately, people in the first stage of the disease are moving about the city, carrying the germs of the disease with them in offices, tram cars, shops, etc.

Discovery of the New Parasite in the Gambia.

A report has been received from Dr. J. E. Dutton and Dr. Todd, the members of the tenth expedition of the Liverpool School of Tropical Medicine, which has been despatched to Gambia and French Senegal to study the new parasite which Dr. Dutton recently discovered in a patient under the care of Dr. Ford, the colonial surgeon of the Gambia. They have found the parasite again in a European and in several natives. The parasite has some resemblance to the tsetse fly, which causes such ravages among cattle in South Africa. Fortu-

nately, it is not so fatal to man. It produces a continuous feeling of illness, with occasional attacks of fever. The researches of the expedition are of importance, as probably many of the cases of West African fevers are due to this new germ. The expedition at present on the Gold Coast is, among other matters, studying the tsetse fly. Dr. Logan Taylor has procured a horse suffering from the disease. There are only two horses at present on the Gold Coast, and it is to one of these that Dr. Taylor refers. He has been instructed to investigate on the Gold Coast the new parasite in man discovered in the Gambia.

Outbreak of Ankylostomiasis in a Cornish Mine.

Dr. J. S. Haldane, F.R.S., has just reported to the government on an outbreak of ankylostomiasis in the Cornish mine at Dolcoath. This is the first outbreak recorded in England. At Dolcoath the patients have been transferred to surface employment or to another shaft, which has usually checked the disease. In England ankylostomiasis is peculiarly a miner's disease, because the low temperature of the outside air is unfavorable to the propagation of the ova of the worm. Dr. Haldane says that the prevention of the disease largely depends on the men themselves taking the proper precautions to prevent pollution of the mine and that unless proper arrangements are made in other mines and carried out by the men ankylostomiasis is likely to spread in England to coal as well as metalliferous mines.

Professor Lorenz in London.

At the City Orthopedic Hospital, before a distinguished audience of the leading surgeons of London, Professor Lorenz, aided by his assistant, Dr. Müller, performed his bloodless operation for the reduction of congenital dislocation of the hip in two cases. He then demonstrated his method of treating congenital club-foot. His remarks, which he gave in English, were frequently received with applause, and his reception was altogether most cordial. The proceedings were opened by Mr. Noble Smith, who, in introducing Professor Lorenz, said that a distinctly adverse expression of opinion on Professor Lorenz's operation had been recently given at the Clinical Society, but that it was the custom in England to give everyone a fair field. Professor Lorenz fully explained his method, which has recently been described in THE JOURNAL.

PARIS LETTER.

Radiography in the French Hospitals.

A committee composed of various physicians and members of the municipal council was formed last December with the object of studying the best means of furnishing the Paris hospitals with apparatus and rooms for radioscopy. At present if a surgeon of the Hotel Dieu wishes to have one of his patients radiographed, he has to make out a demand, which is given to the director, forwarded to the chief of laboratory at the Salpêtrière Hospital, who comes to the Hotel Dieu with all his instruments, and later sends the surgeon a proof. The subject was discussed at the municipal council and the proposition was rejected, a fact which will not prevent some physicians from installing the apparatus at their own expense, as, for instance, Variot has done at the Enfants' Malades Hospital.

Treatment of Boils by Iodin.

Dr. Gallois has found that a solution of 4 gm. iodin in 10 gm. acetone is very serviceable in the treatment of boils. Dr. Castillon prefers a solution containing one part of iodin to two of glycerin, as it is much less irritating. This solution is obtained by heating glycerin and iodin under pressure at a temperature of 120 or 150 degrees.

New Method of Finding the Tuberculous Bacillus.

Dr. André Jousset recommends a new method for finding the bacillus of Koch in certain morbid secretions, which applies more especially to fibrinous effusions of the pleura. It consists in liquefying the coagulum by means of an artificial gastric juice containing fluor, and centrifuging. In this manner all solid substances not attacked by the gastric juice, such as the bacillus, are assembled in the deposit and can be readily colored. By means of this technique, Dr. Jousset has been able to find the bacillus of Koch twenty times in twenty pleuritic effusions, six times in tuberculous peritonitis and twice in the blood of patients suffering from acute consumption. The same method has also been used by Dr. Besançon and Griffon, only instead of using gastric juice they employ solution of soda.

Correspondence.

Membership in the American Medical Association and the New York Profession.

CHICAGO, Jan. 23, 1903.

To the Editor:—I send herewith, for publication in THE JOURNAL, a copy of my reply to a letter received from a New York physician. It explains itself. I have purposely gone into details with the intention of publishing the matter. I have done so for the reason that I feel that there is a misunderstanding on the part of some of the members of the profession, especially in New York, as to the position held by the American Medical Association in regard to the conditions in that state.

Very truly yours,

FRANK BILLINGS.

CHICAGO, Jan. 20, 1903.

Dear Doctor:—Your letter of recent date to the Secretary of the American Medical Association, concerning your relations with that body, has been handed to me with the request that I reply.

In the letter you say that you wish to sever your relationship with the American Medical Association, because of the actions of the Association. You state that the conduct of the Association is narrow, that this is 1903, not 1880 or 1881, and that as long as the American Medical Association continues to make an unjust and particular target of the New York State Society, so long must you forego the pleasure of membership in it.

I am induced to make reply to this letter for the reason that you make the statement "the American Medical Association makes a target of the Medical Society of the State of New York," and that I may explain to you and to other members of the New York profession the present status of the American Medical Association and its relation to the profession of New York.

In the first place, I desire to state to you that this is 1903, and not 1880 or 1881, and I do not wish to discuss the issues of twenty-two years ago, but to take up the affairs of the American Medical Association and its objects since the plan of reorganization.

At St. Paul, in 1901, the Association adopted a plan of reorganization and a Constitution and By-laws which embodied the plan which will be pursued in the future in an attempt to organize the profession of the United States on a broader plan than has heretofore existed.

I shall not attempt to give you the Constitution and By-laws for you may read that document. Suffice it to say that one of the principles of reorganization is the formation of a county society in each county of each state, so far as practicable, the members of which shall form a state association, and that the members of the different state associations shall constitute the membership of the American Medical Association. The county society is the initial unit, and under this plan is the portal of entry to membership in both the state and national bodies. This plan embraces, of course, the principle that there shall be but one recognized county society in a county, and but one state association in a state in affiliation with the national organization.

The committee of the American Medical Association which formulated the plan of reorganization was continued and later formulated a "Constitution and By-laws for County Societies," and also one for state societies which agrees with the principles mentioned above and corresponds with the Constitution and By-laws of the American Medical Association.

Ten or more of the different states have since adopted the Constitution and By-laws recommended by the Committee on Reorganization, and many counties of the different states have adopted the Constitution and By-laws recommended by the committee. Reorganization is thus going on all over the country, to a greater degree than the most ardent supporter of the reorganization plan could have hoped, and the outlook now is that within a very few years the profession of the United States will be organized on the plan embodied in the Consti-

tution and By-laws of the St. Paul meeting and we shall be a united profession.

In almost every state of the Union there are physicians who have continued to be listed as members of the American Medical Association, although they are not members of the local society or of the state society in affiliation with the American Medical Association. These physicians are therefore not legal members of the American Medical Association. Furthermore, there was no inducement for them to become members of the affiliated bodies in the state in which they lived so long as they were carried on the list of members of the American Medical Association and enjoyed all the privileges of that body.

A committee was appointed at Saratoga to look up this matter of membership, which recommended that on or about Jan. 1, 1903, the Secretary of the American Medical Association should notify every physician in the different states who was not a legal member according to the Constitution and By-laws, that his name would be dropped from the list of members if he did not become a member of an affiliated society on or before March 1, 1903.

This action was not aimed at the physicians of the state of New York, but was intended (as indicated above) to correct an error where it existed in all of the states of the Union.

However, in New York state a worse condition prevailed than elsewhere for the reason that two state organizations have existed there since 1884.

As you know, the Medical Society of the State of New York ceased its affiliation with the American Medical Association in 1882 because of the existence of the Code of Ethics adopted by the Association in 1847.

Although the Association adopted a new Constitution and By-laws at St. Paul in 1901, it did not in any way alter the Code of Ethics, which was continued as the ethical expression of the Association. However, the sentiment apparently of the country in reference to the code was such that at the Saratoga meeting in 1902 a draft of a revised Code of Ethics was introduced to the House of Delegates and met with much favor in that body and from the members as a whole. A committee was appointed to present a revised code at the New Orleans meeting, and that document will be acted on by the House of Delegates in May of this year.

In February, 1902, the president of the Medical Society of the State of New York wrote to the president of the New York State Medical Association, informing him that the medical society, at its meeting held the latter part of January, 1902, had adopted a resolution that a committee of five be appointed to confer with a committee representing the New York State Medical Association for the purpose of formulating a plan which should have for its object the reorganization of the regular medical profession of the state of New York into one body, which body would be in affiliation with the American Medical Association. After considerable correspondence between the presidents of the two state medical bodies of New York, a committee of five from each was formed. From the Medical Society of the State of New York the committee was Drs. Henry L. Elsner, chairman, A. Jacobi, A. Van der Veer, A. M. Phelps and George Ryerson Fowler; from the New York State Medical Association: Drs. E. Elliott Harris, chairman, Frederick Holme Wiggin, Emil Mayer, Parker Syms and Wm. H. Biggam.

By correspondence and by conference these committees agreed on certain propositions which were signed by the chairman of each committee.

In brief, the propositions which were adopted were as follows:

First. There is an honest desire on the part of the members of the two state organizations to unite the regular medical profession of the state.

Second. That they organize by the legal union into a single state medical body, to be known as the Medical Society of the State of New York, of which all members in good standing in both organizations should be charter members.

Third. That the reconstituted medical body should be the representative in the state of the American Medical Association by virtue of the acceptance of the Constitution and By-laws of the American Medical Association.

At a meeting of both the committees, held April 18, 1902, the question of the manner of preparing the charter of the new organization was taken up, and the preamble and proposed charter which embodied the agreements above mentioned were read and adopted and signed by the chairman of each committee. (See the *New York State Journal of Medicine*, pp. 308 to 313 inclusive, November, 1902.)

At the joint conference of the committees held at the Academy of Medicine in New York City Oct. 3, 1902, the committee of the Medical Society of the State of New York stated that they could not recommend the acceptance by the state society of the By-laws of the American Medical Association containing Article XV. (Art. XV of the Constitution and By-laws, among other things, affirmed the Code of Ethics of the American Medical Association.)

At the Saratoga meeting the Constitution and By-laws were somewhat modified and, among other things, Article XV was omitted.

At the meeting of the New York State Medical Association in October, 1902, the committee of the association made its report concerning the result of its conference with the committee of the state society.

This was, in short, that the two committees had agreed that they would attempt to unite the regular profession of the State of New York into one body to be known as the Medical Society of the State of New York, of which all members of both societies in good standing should be charter members, and the reconstituted state medical body should be the representative in New York state of the American Medical Association by virtue of its acceptance of the Constitution and By-laws of the American Medical Association. This report of the committee was accepted with the expression of the New York State Medical Association of a sincere desire for a union.

In addition to this a resolution was adopted that the committee of the association should be continued for the purpose of co-operating with any committee from the Medical Society of the State of New York to secure a charter from the legislature during the session of 1903.

The resolution further stated that if the Medical Society of the State of New York should fail to approve of the plan of the union agreed on between the two committees, including the adoption of the Constitution and By-laws of the American Medical Association, in such time as would enable the proper committees to obtain a charter from the legislature in 1903, that the committee of the association should be discharged and the proposition for the union should be withdrawn.

This action of the association left its special committee on conference in abeyance until such time as the committee of the society or the society itself could agree in full to the propositions made in joint committee meeting.

This status of affairs has continued in New York since the date of the meeting of the joint committee on Oct. 3, 1902, or perhaps it would be better to say since the meeting of the New York State Medical Association later in October.

The Secretary of the Association, Dr. Geo. H. Simmons, and I had conferred concerning the effect of the notice which, as stated above, was to be sent by him to the physicians who were listed as members of the American Medical Association in the different states, but who were not legally members of the Association. As there were nearly one hundred and fifty of these in New York state, the greater number of whom were members of the Medical Society of the State of New York, it made the situation there of greater import than in any other state of the Union.

It therefore seemed wise to Dr. Simmons and to me that I, as President of the Association and as an outsider, should go to New York and, if possible, confer with the two committees for the purpose of hastening legal union of the two bodies. If this could be accomplished before the first of March all of the listed members could then become legal members of the Association; and if it could be accomplished before the first of January none of them would receive a notice from the Secretary as mentioned above.

Accordingly I communicated with the chairman of each committee, with the result that a meeting of a full membership of

each committee with me was held at 3 o'clock on Friday, December 19, at the Academy of Medicine in New York City.

The chairman of the committee of the New York State Medical Association stated to me that his committee was in abeyance by the action of the state association and could not discuss the question at issue, inasmuch as the propositions for a union had been made by the association and that the most of the propositions had been accepted by the committee of the society, and at this time awaited only the acceptance by the committee of the society of a signed agreement to accept the Constitution and By-laws of the American Medical Association. That if the Medical Society of the State of New York should accept the report of its committee of its society, including the agreement to acknowledge the Constitution and By-laws of the American Medical Association at its meeting in January, 1903, then the committee of the association would become active again and be ready to co-operate with a committee of the society to secure a charter and legalize the union of the regular profession under one society as mentioned above.

In the conference I found the gentlemen of the two committees kind and courteous, and the most cordial and kind consideration was shown to me and to the members of the two committees by each individual present.

I made a preliminary statement, in which I said that the committee of the state association, through its chairman, had indicated to me that his committee could not enter into a discussion of the propositions for union because they were in abeyance and also for the reason that the propositions had been accepted by the state association and required no further discussion from them as a committee.

I also outlined the status of conditions in New York, naming step by step the propositions which had been advanced and accepted by the two committees to the time of their last joint meeting on October 3. In addition to this, the statement was made of the acceptance by the state association of the propositions. I also stated that the object of the meeting was to confer about existing conditions in the state of New York, and that I hoped no discussion of the problems of 22 years ago would come up, as I felt there was nothing to be gained thereby.

Inasmuch as a discussion of the meaning of Article XV of the Constitution and By-laws had been questioned after it had been omitted from the Constitution in 1902, I made the statement that the omission of Article XV did not in any way alter the relation of the Code of 1847 to the American Medical Association. That without Article XV the code was as much a part of the Association as before.

In answer to my preliminary remarks, Dr. Henry L. Elsner, chairman of the committee of the society, made the following statement. I do not attempt to quote his exact words, but in brief he said:

First, That since the conference of the two committees, conditions had occurred which made the committee of the Medical Society of the State of New York alter its attitude in reference to the propositions made for a union of the two organizations into one legal body.

Second, That the committee of the society could not now agree to the proposition of the union on the basis of the abandonment of the charter of the Medical Society of the State of New York; that the charter of the society, granted in 1806, contained many valuable provisions which their legal advisor had informed the committee could not be secured, at the present date, from the legislature of the state. That the traditions of so old a society, in addition to its many privileges, should not be given up. That the society would be willing to receive the members of the association in good standing into its body in lieu of the members of the two societies becoming charter members in the proposed new society.

Third, That the society could not afford to amalgamate with the association in obtaining a new charter for the reason that the new body would assume necessarily the debts and obligations of each of the existing state bodies. That the financial condition of the association was such that the society could not afford to assume the risk of its debts.

Fourth, That the committee of the society was not willing to accept the Constitution and By-laws of the American Medical Association or to recommend its acceptance to the Medical Society of the State of New York with the understanding that the Code of Ethics of 1847 was still in existence.

I then made the additional statement that the status of the Code of Ethics differed only from that of 21 years ago in this: That at the St. Paul meeting in 1901, when the new Constitution and By-laws were adopted, the clause in the old Constitution and By-laws which made it necessary for every medical body affiliated with the Association to adopt the Code of Ethics was dropped. That since 1901, therefore, while the code existed it was not now necessary that a county or state society in affiliation with the American Medical Association should adopt the code. That such affiliated bodies could organize without a code at all or with a code differing from that of the American Medical Association. I stated that Illinois and Ohio had no code, and that Massachusetts and possibly one other state had a code of its own. That doubtless other states and county societies existed without a code or with a code differing from that of the American Medical Association. That it was, therefore, perfectly feasible for the two state medical bodies of New York to unite on the propositions made and agreed on at former conferences to secure a charter from the state legislature and to organize a body which should be the representative in the state of the American Medical Association without a code or with a code formulated to suit themselves. That if they did so unite before the meeting of the Association in New Orleans, their delegates—who would doubtless be men now representing both the society and the association—could go to New Orleans and help in formulating and adopting a revised code.

Dr. Jacobi, a member of the committee of the society, also spoke in substance as follows:

That he, as a member of the committee, would not agree to the propositions for a union so long as the present code of the Amedical Medical Association existed. That if a revised code, as was introduced at Saratoga, were adopted by the American Medical Association, it would be acceptable to him—as it doubtless would be to the other members of the state society—although it contained objectionable features.

But, said Dr. Jacobi, if the American Medical Association is now of the opinion that it should have a revised code, or if at the New Orleans meeting the old code is abrogated or a revised code is adopted, then the American Medical Association will confess that it was wrong and the Medical Society of the State of New York was right twenty-two years ago. That he would not consent to a union of the two bodies or become a member of the American Medical Association so long as the old code existed. That if at New Orleans a revised code, such as was introduced at Saratoga, were adopted, that by this act the American Medical Association would confess its error in the past and could in justice do no less than invite the Medical Society of the State of New York to become again the one affiliated state medical society in New York. That the state society would then be ready and willing to receive the regular members of the profession in the state of New York, including those of the association, as members of the Medical Society of the State of New York.

The committee of the association was in abeyance and had no answer to make to the statement of the committee of the society.

There was, therefore, nothing gained by the conference excepting this: That the position of the committee of the association and its members and of the committee of the society was made distinct and plain.

Before we separated I summed up the situation by the statement that the association, through its committee, had adopted certain propositions for a union such as are outlined in this letter. That the committee was in abeyance and would become active again provided the society would accept the propositions at a date early enough to enable the joint committee to secure a charter from the legislature of 1903. That the association had put this time limit on the society, not to force them to action, as I understood it, but so that if it was not accepted

by the society, the association could then go on at the earliest possible date and reorganize the profession of the state in the different counties as the recognized state body.

At this point a member of the committee (I think Dr. Jacobi) made the statement that the committee of the society did not desire the association to stand still, but would be pleased to have them go on and organize the profession of the state without reference whatever to the negotiations going on.

As to the society, I summed up the propositions as made above by Dr. Elsner as the status of that committee.

I also said that it seemed to me the only hope of the union of the two state bodies this year was to be accomplished on the following plan: That the committee of the society should make its report to the Medical Society of the State of New York at its January meeting and ask for further time to consider the propositions of the association. That inasmuch as the committee had unanimously agreed not to adopt the Constitution and By-laws of the American Medical Association now or as long as the Code of Ethics existed, that if at New Orleans the revised code was adopted and was acceptable to them, that they could then adopt the Constitution and By-laws and with it the revised code. That they could perhaps make provisions at the meeting of their society in January whereby an official body or committee could then accept, with power to act, the completed report of the committee for amalgamation of the two state bodies. That this act would make the committee of the association active and that together with the committee of the society they could then go on and secure a charter during this year.

This is a statement of the status of affairs in New York State made by an unprejudiced outsider and by one who has been and is most anxious that the profession of the Empire State should be united in one body representing the whole profession of the state in the American Medical Association.

The American Medical Association is most anxious to have the good men of the profession everywhere in its membership. And I want to repeat that no target is made of the members of the Medical Society of the State of New York. It is simply a question of adjustment of the differences between the members of the profession in New York and that they must themselves settle.

I am sure you and every other member of the Medical Society of the State of New York will find that the great body of members of the American Medical Association are desirous of having you back as members and that we are willing and desirous of helping you as far as we can. But the members of the Medical Society of the State of New York must come to the American Medical Association, and should not for a moment believe that the American Medical Association will go to them.

In conclusion it must be distinctly understood that the New York State Medical Association is the only affiliated state body in New York, and as such, the only one that the officers of the American Medical Association can recognize.

Believe me, Very sincerely yours,

FRANK BILLINGS,
President of the American Medical Association.

A Side Light on Ethics.

PHOENIX, ARIZ., Jan. 17, 1903.

To the Editor:—Referring to the communication of Dr. Gillmore in THE JOURNAL, January 3, "A Side Light on Ethics," I would like to say that the Eminent Consultant is not only responsible for the "bulldog tendency" of to-day, but also for the increase of the horde of medical Arabs who, finding it difficult to be honest with the profession or public, and live, scour the deserts and cities, seeking whom they may devour.

The Eminent Consultant of the species described by Dr. Gillmore is a reproach to the profession, and does more to bring discredit on the profession and break up professional unity, nullify professional organizations and destroy charity than do the fakers and medical parasites.

I would submit as a remedy for this disease one which, though it may seem heroic and in itself subversive of some of the tenets of the Code it is intended to preserve, at the same time might prove curative. Perilous diseases sometimes require heroic remedies, and a rule of conduct was never made that was intended to shield or protect the guilty.

The remedy that I would suggest is publicity, at least among properly constituted authorities. Neither the public nor the profession as a whole are so strabismic but that they are able to view things in their proper proportions if given a fair chance. The trouble is the medical code is so interwoven with mysteries of "Thou shalt not," and "Under my grace and guidance thou mayest," that no wonder the tender shoots in the medical profession are apt to become dwarfed and stunted.

The injury done Dr. Gillmore in a case cited might be reckoned from the commercial standpoint in the hundreds and thousands, but he has no recourse in the medical courts of law at present constituted.

There is an eminent surgeon living to-day in one of the principal cities of the country who outdoes Dr. Gillmore's Eminent Consultant. The case was this: A reputable physician, graduate of one of the best schools in the country, and who had, at the cost of the usual amount of time and hard work, fitted herself for the practice of surgery, came to the city in which the Eminent Consultant was a resident and practitioner. Being a stranger, Dr. Brown (this is an *ex-parte* statement) introduced herself and presented her credentials to the Eminent Consultant and asked him if he would accord her the grace of his presence, advice and assistance in a surgical procedure on a private patient of her's, the operation to be performed in one of the leading hospitals of the city. The Eminent Consultant, Dr. Black, consented to furnish all these elements of grace with the following proviso: Dr. Brown was to do the operation, assuming all the responsibility that goes with it, but in the case-book the record should read Drs. Black and Brown, and Dr. Black was to pocket two-thirds of the fee.

If this were not related by one credible witness, one of the parties in the case, it would hardly be believable. Leaving out of consideration the matter of professional ethics and placing the case on the basis of ordinary commercial or business ethics, one would feel that a man who would treat a woman in that manner was hardly deserving of respect, much less of retaining his exalted position in the local profession. In this case Dr. Brown was helpless, and the operation was concluded on the terms proposed.

A friend of mine who was making a specialty of abdominal surgery in a small town neighboring Philadelphia, called in an Eminent Specialist residing in the latter city to consult with him in a desperate case, which proved to be general puerperal peritonitis with free pus throughout the abdominal cavity. The Eminent Consultant, after admitting to a member of the patient's family that my friend was properly qualified to perform such surgical procedure as the case might require, came down to the consultation armed with full paraphernalia for performance of same and with intent to do the operation. When informed that he had simply been called at the family's request as consultant he went off in a huff, and afterwards, as I have been informed, said some very harsh things reflecting on the ability of the operator and in regard to the termination of the case, which was death.

W. H. BURR.

State Boards of Registration.

Rhode Island.—Dr. Gardner T. Swarts, secretary, reports the Rhode Island State Board of Health to have held an examination at Providence, Jan. 2 and 3, 1903, in which the number of subjects was 7; questions, 70; percentage required to pass, 75; written examination; number examined, 9; passed, 7; failed, 2.

PASSED.

Candidate.	Sch. of Pract.	College.	Year Grad.	Per Cent.
194	R.	University of Vermont	1902	79.0
196	R.	University of Edinburgh	1891	88.2
198	R.	Coll. of Phys. and Surgs., Baltimore.	1901	81.6
200	R.	College of Phys. and Surgs., Chicago	1890	79.4
199	R.	Tulane University	1896	85.4
201	R.	McGill University	1902	87.3

† Failed twice.

Queries and Minor Notes.

ANONYMOUS COMMUNICATIONS will not be noticed. Queries for this column must be accompanied by the writer's name and address, but the request of the writer not to publish his name will be faithfully observed.

IMPROVED TREATMENT OF EMPYEMA.

COLDWATER, MICH., Jan. 24, 1903.

To the Editor:—I see in THE JOURNAL of January 17 a comment on improved treatment of empyema, wherein you state "so far as we have seen this particular operation has not been recommended by any other operator."

I desire to say that I have used a similar method for several years past and am greatly pleased to learn that Dr. Ingals approves of the method. Enclosed find reprint in verification of priority of method. Respectfully, D. H. WOOD.

NOTE.—The reprint is from the Proceedings of the Michigan State Medical Society, 1889, and is in line with Dr. Ingals' suggestion. The latter, however, thinks that better results are obtained where two tubes are used instead of one.

MEDICAL PRACTICE IN CUBA.

LOUISVILLE, KY., Jan. 20, 1903.

To the Editor:—Will you kindly give me the requirements for practicing medicine in Cuba? X.

ANS.—To obtain permission to practice medicine in Cuba, one must first submit his diploma to the Superintendent of Public Instruction and undergo examination by a committee appointed by the University of Havana. The examination will have to be in Spanish, though an interpreter is allowed. The examinations include not only oral, but written theses and examining of cases.

Marriages.

HARRY S. SWOPE, M.D., Louisville, Ky., to Miss Bettie Pegg of Wheatley, Ky.

GEORGE HEUSTIS FONDE, M.D., to Miss Mary Crawford, both of Mobile, Ala., January 8.

ALDEN RAY DENNY, M.D., Galesburg, Ill., to Miss Susan T. Gould of Chicago, January 7.

OWEN W. GRUBBS, M.D., to Miss Florence Baughman, both of Harrison, Ohio, January 6.

WILLIAM V. BRYANT, M.D., Madison, Wis., to Miss Franc C. Taylor of Chicago, January 8.

VAN A. STILLEY, M.D., Benton, Ky., to Miss Mae Coleman of Princeton, Ky., January 15.

JOHN WEST BENTON, M.D., Ogdensburg, N. Y., to Miss Harriet Egert, in London, England.

JOHN A. PRINCE, M.D., Springfield, Ill., to Miss Eva Cross of Mechanicsburg, Ill., January 14.

ROLLIN P. COLLINS, M.D., Bishopville, Md., to Miss Nellie Cannon of Frankford, Pa., January 15.

GUS A. BACHMANN, M.D., Dorr, Mich., to Miss Bertha Leow of Burnips Corners, Mich., January 21.

PAUL STAFFORD MITCHELL, M.D., Iola, Kan., to Miss Grace Jaquess of Hammond, Ill., Dec. 25, 1902.

WILLIAM ELLERY JENNINGS, M.D., to Mrs. Marie Taggart Ropes, both of Brooklyn, N. Y., January 6.

VACLAV PODSTATA, M.D., Kankakee, Ill., to Miss Mary Graham Porter, at Lawton, Okla., January 12.

EDWARD WEBBER, M.D., Sebewaing, Mich., to Miss Clara Rosina Foerster of Ann Arbor, Mich., January 14.

Deaths.

Edward T. Dickerman, M.D., one of the most promising young physicians of Chicago, died at the residence of his mother in Springfield, Ill., January 23, from pneumonia, aged 35. He was born in Jacksonville, Ill., Aug. 4, 1867, began his medical studies in Chicago Medical College in 1887, and was graduated from that institution in 1890. He gained an interneship in Mercy Hospital, and served acceptably in that position. At the conclusion of his term of service he continued his studies in Europe, devoting his attention especially to the ear, nose and throat. On his return to Chicago he commenced practice in this specialty, and speedily acquired a large practice. On January 17 he went to Springfield to operate, and on the next day had a chill and symptoms of pneumonia. The disease ran a rapid course, and despite the best and most affectionate care, he died five days later. He was a member of the American Medical Association, American Laryngological Association, Illinois State Medical Society, Chicago Medical Society, and the Physicians' Club, and a fellow of the Chicago Academy of Medicine. He held the positions of professor of laryngology at the Chicago Policlinic, and associate professor of otology, Rush Medical College, and was attending ear surgeon at the Illinois Charitable Eye and Ear Infirmary. His funeral at Springfield, January 25, was attended by a number of Chicago physicians, and the faculties of Rush Medical College and the Chicago Policlinic sent floral tributes. At the meeting of the Physicians' Club, January 26, Dr. Dickerman's death was formally announced, and expressions of regret and sympathy were adopted.

Eli H. Coover, M.D. Jefferson Medical College, Philadelphia, 1850, a member of the American Medical Association, Medical Society of the State of Pennsylvania, Dauphin County Medical Society, and founder and first president of the Harrisburg Academy of Medicine, died at his home in Harrisburg, Pa., after a long illness, January 13, aged 75. He was esteemed, honored and beloved as a physician. As a citizen he was public-spirited, and a few years ago presented a park to Harrisburg. At special meetings of the Harrisburg Academy of Medicine and of the Dauphin County Medical Society resolutions of eulogy and sorrow were passed, and the members attended the funeral in a body.

Anson Soverille Fraser, M.D. Faculty of Queen's University and Royal College of Physicians and Surgeons, Kingston, died at his home in Sarnia, Ont., from Bright's disease, Dec. 31, 1902, aged 56. He was one of the best-known and prominent physicians of Western Ontario; and from 1891 to 1899 was examiner for the Ontario Medical Council in physiology. He was largely instrumental in establishing the Sarnia General Hospital in 1896, and was president of the hospital board up to last November.

James M. Alexander, M.D. University of the State of Missouri, Columbia, 1886, died at his home in Anabel, Mo., from pleurisy, January 13, after an illness of several months, aged 40. At the meeting of the Macon County Medical Society in Macon, January 16, a committee was appointed to draft resolutions regarding the death of Dr. Alexander.

Susan R. Pray, M.D. Women's Medical College of the New York Infirmary, 1882, for 3 years a medical missionary in China, died at her home in Brooklyn, January 14, after an illness of two months, aged 45. She was a member of the Brooklyn Health Board for 13 years, and was a member of the American Medical Association.

Will C. Cundiff, M.D. Vanderbilt University, Nashville, Tenn., 1900, died at his home in Somerset, Ky., from tuberculosis, January 6. At a meeting of the Pulaski County Medical Society, January 8, a tribute to Dr. Cundiff's memory was adopted.

Robert H. Goldsmith, M.D. University of Maryland, Baltimore, 1852, some-time physician to Bayview Hospital and president of the Alumni Association of the University of Maryland School of Medicine, died suddenly at Baltimore, January 13, aged 70.

Alexander T. Gordon, M.D. Medical College of Virginia, Richmond, 1858, surgeon of Pegram's Battalion, C. S. A., in the Civil War, died at his home near Lignum, Culpeper County, Va., January 14, after an illness of several years, aged 70.

George F. Motter, M.D. University of Nashville (Tenn.), 1864, who served during the Civil War as a surgeon in the Federal Army, died at his home in Taneytown, Md., from pneumonia, after an illness of two weeks, aged 60.

Frederick J. Bancroft, M.D. University of Buffalo, 1861, a surgeon in the Army during the Civil War, for the past 37 years a resident of Denver, died from heart disease at San Diego, Cal., January 16, aged 69.

John Allard Jeancon, M.R.C.S. Eng., 1854, surgeon of the Thirty-Second Indiana Volunteer Infantry in the Civil War, died at his home in Newport, Ky., January 13, from pneumonia, after a long illness, aged 74.

David C. Bryan, M.D. Central College of Physicians and Surgeons, Indianapolis, 1887, died from paralysis at his home in Hot Springs, Ark., January 14, after an illness of two months, aged 42.

George W. Harding, M.D. Rush Medical College, Chicago, 1900, a missionary of the American Board, died at his station in Ahmednagar, Bombay Presidency, India, January 14, of septicemia.

Isaac H. Shields, M.D. University of Pennsylvania, Philadelphia, 1860, who served throughout the Civil War, died from rheumatism at his home in Philadelphia, January 13, aged 64.

William H. Hildreth, M.D. Dartmouth Medical College, Hanover, N. H., 1868, died at his home in Newton Upper Falls, Mass., January 15, after a short illness, aged 65.

John H. Xelowski, M.D. College of Physicians, Chicago, 1900, of Oklahoma City, Okla., died at St. Mary's Hospital, Decatur, Ill., January 16, from heart disease.

John W. Hignutt, M.D. Jefferson Medical College, Philadelphia, 1856, who retired from practice in 1893, died at his home in Hickman, Del., January 12, aged 73.

Thomas B. Bush, M.D. Atlanta (Ga.) Medical College, 1894, died at his home in Lawrenceville, Ga., January 11, after a long illness, from typhoid fever, aged 33.

George N. Gage, M.D. Boston University School of Medicine, 1877, died from consumption at his home in East Washington, N. H., January 10, aged 51.

George W. Howard, M.D. Medical College of Virginia, Richmond, 1863, died at his home in Vicksburg, Miss., January 11, after a long illness, aged 68.

Charles H. Hedges, M.D. Jefferson Medical College, Philadelphia, 1841, died at his home in Charlottesville, Va., January 12, after a long illness, aged 84.

Peter Root Everett, M.D. Jefferson Medical College, Philadelphia, 1856, died at his home in Cleveland, Ohio, January 13, after a short illness, aged 68.

Louis A. Burgess, M.D. Tulane University, New Orleans, 1856, died at his home in New Iberia, La., January 15, after a long illness, aged 72.

Walter F. Randolph, M.D. Rush Medical College, Chicago, 1870, of Bedford, Iowa, died at the home of his daughter in Chicago, January 4.

Charles B. Adams, M.D. University of Louisville (Ky.), 1898, of Vanceburg, Ky., died, January 14, at a hospital in Portsmouth, Ohio.

Richard S. Markell, M.D. McGill University, Montreal, 1867, died from apoplexy at his home in Cloverdale, Cal., January 10.

Andrew J. Burrus, M.D., of Dallas, Texas, was struck by a passenger train, January 11, and instantly killed.

Henry W. Day, M.D., registrar of Hastings County, Ont., died at Belleville, January 10, aged 71.

Deaths Abroad.

Samuel Fenwick, M.D., F.R.C.P., the well-known writer on gastric disorders, has died at the age of 72. He was a Northumbrian, and was apprenticed to the Royal Infirmary, Newcastle-on-Tyne. After obtaining the membership of the Royal College of Surgeons he soon acquired one of the largest practices in the northern counties. For some years he lectured at the University of Durham Medical School. Forty years ago he removed to London. He first became connected with the City of London Hospital for Diseases of the Chest. In 1868 he was appointed on the staff of the London Hospital, on which he remained until he retired in 1896. There he made his reputation as a teacher and clinician. Despite a large practice and his hospital duties, he found time to make several valuable scientific researches, the most important of which was, perhaps, the significance of the presence of sulphocyanid of potassium in the saliva in various diseases. His "Students' Guide to Medical Diagnosis" was popular with many generations of students, and in its time was recognized as the best manual to place in the hands of the student beginning to work in the wards. In teaching, Dr. Fenwick insisted on the importance of accuracy of observation and of the students recording what they saw as the best way of becoming good diagnosticians. He wrote: "A number of well-recorded cases is invaluable, and forms the best practice of physic for your future reference and guidance." In 1879 he published "Outlines of Medical Treatment," which in a few years passed through four editions. As a writer on digestive maladies he made his reputation. He wrote the article on diseases of the stomach in the first edition of Quain's *Medicine*. During the last four years he was preparing a series of monographs on diseases of the stomach and completed the first two, which dealt with "ulcer" and "tumor."

Dr. Panas, the well-known ophthalmologist and surgeon of Paris, at one time president of the Académie de Médecine. He was a Greek, born in the Ionian Isles in 1831, but was educated in France, and became interne, demonstrator of anatomy, prosector, then professor agrégé and surgeon to the hospitals, and was finally appointed in 1879 to the newly-organized chair of ophthalmology. There are few questions in ophthalmology to which he has not brought some important contribution. His name is particularly connected with his method of tenotomy, his operations for ptosis, strabismus, cataract and neoplasms of the eye, and his studies on interstitial keratitis and glaucoma. His Manual of Ophthalmology is a classic. He was "chef de service" at the Saint Louis Hospital during the siege of Paris, and served also as volunteer surgeon in the barracks, while at the same time he was holding daily thronged eye clinics, and was studying German. During the Greco-Turkish war he organized and personally took charge of a relief ambulance. These experiences and his vast learning, his knowledge of the ancient classics and long training in anatomy and general surgery, his alert clinical sagacity, marvelous technic and imperturbed *sang froid*, combined to place him in the front rank.

Dr. H. Varnier of Paris, a prominent specialist and writer on obstetrics. His mother died in childbirth, and he devoted his life to reducing the mortality from this cause. He published, among other works, an atlas of pathologic obstetric anatomy in collaboration with Pinard, and in 1900 a fine illustrated manual on obstetrics in daily practice.

Dr. A. Kast, professor and director of the medical clinic at Breslau, aged 47, of a protracted renal affection.

Miscellany.

The Famous Plague Song.—Flexner remarks, as previously mentioned,[1] that the plague has gained admittance into our midst, and that it is the first time in history that the Western Continent has been invaded. He gives the words of the Augustin song which few realize dates from the great plague epidemic in Europe centuries ago. Augustin was a wandering minstrel, whose occupation was interrupted by the prevalence of the plague, and his plaint is a classic in German student

1. See THE JOURNAL, Dec. 6, p. 1485.

circles. The tune is familiar everywhere. The original is as follows:

Oh, du lieber Augustin,
's Geld ist hin, d'Freud' ist hin,
Oh, du lieber Augustin,
Alles ist hin!

Ach, und selbst das reiche Wien
Arm jetzt wie Augustin,
Seuftzt mit mir in gleichem Sinn,
Alles ist hin!

Jeden Tag war sonst ein Fest;
Und was jetzt? Pest, die Pest!
Nur ein grosses Leichennest,
Das ist der Rest!

Oh, du lieber Augustin,
Leg nur ins Grab dich hin,
Ach, du mein liebes Wien,
Alles ist hin!

This may be freely translated thus: "Oh, you dear Augustin. There is no money, there is no pleasure. Everything is gone! Even wealthy Vienna is as poor now as Augustin, and laments with me that everything has gone to pieces. Every day used to be a festival, but now, plague take it, the plague! Nothing but a great nest of corpses! Oh you poor Augustin, go lie down in your grave. Alas, my beloved Vienna, the bottom has dropped out of everything!" Those familiar with Chicago will recognize in this the original of "Ach, du lieber Halsted Street," the local song concerning that notable thoroughfare.

Association News.

EXCURSION RATES—NEW ORLEANS MEETING.

Rules Governing Extension of Tickets.

SOUTHERN PASSENGER ASSOCIATION.

ATLANTA, GA., Jan. 22, 1903.

To the Editor:—Referring to previous correspondence in regard to reduced rate and arrangements for the above meeting in New Orleans in May, attached please find copy of Passenger Tariff Exc.-1670, which shows detailed information as to special agency extension arrangements, etc. It may help your attendance to give this feature a wide circulation, as I have no doubt many of the delegates to your meeting will wish to make side-trip excursions. Very respectfully,

JOSEPH RICHARDSON, Chairman.

Passenger Tariff No. Exc.-1670.

Supplementing Passenger Tariff No. Exc.-1646. (*See* THE JOURNAL, *Jan. 8 p. 46.*)

The rules and regulations herein published are the separate rules and regulations of each of the following individual carriers and its connections:

Illinois Central Railroad.
Louisville & Nashville Railroad.
New Orleans & Northeastern Railroad.
Yazoo & Mississippi Valley Railroad.

RULES AND REGULATIONS.

The final limit of all tickets sold at the rate published in Passenger Tariff No. Exc.-1646 will be ten (10) days from date of sale, but original purchasers of such tickets may secure an extension of this final limit by personally depositing their tickets with Joseph Richardson, Special Agent, Room 204, No. 204 Camp Street, New Orleans, between the hours of 8 a. m. and 8 p. m., not earlier than May 1, nor later than May 12, 1903, and on payment of fee of fifty cents per ticket at time of deposit, at which time a receipt reading as follows will be issued:

NEW ORLEANS, LA., ——, 1903.

On presentation of this receipt to the undersigned at room 204, No. 204 Camp St., New Orleans, La., between the hours of 8 a. m. and 8 p. m., on or before May 30, 1903, by the original purchaser (in person) of ticket deposited this date for extension and covered by this receipt, ticket so deposited will be returned to original purchaser with the final limit extended so as to enable the original purchaser to leave New Orleans, La., on the date said ticket is withdrawn from deposit and travel by continuous passage through to the original starting point, but in no case will such final limit be extended to reach original starting point beyond midnight of May 30, 1903.

Original purchaser of ticket must present this receipt in person. Embossed signature of Special Agent.

When the original purchaser is ready to resume his journey and withdraws his ticket from deposit the Special Agent will attach an extension paster. These extension pasters will be printed on the Perfect Safety Paper adopted as standard by the American Association of General Passenger Agents and bearing water mark consisting of a star and the letters AA-GP-TA. In placing his signature on the back of the extension pasters, the Special Agent will in all cases use a facsimile embossing stamp. JOSEPH RICHARDSON, Chairman.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

The following letter is being sent to all physicians who are listed as members of the American Medical Association and who do not belong to an affiliated society in the state in which they live. The letter is published so that those interested may be informed, as it will be impossible to reach all by the first of March, the time specified in the resolutions. To save unnecessary correspondence the following information is given:

1. To retain membership in the American Medical Association it is obligatory that a physician be a member in good standing of the state society of the state in which he resides, or in one of its recognized branches. A physician is supposed to reside in the county in which he votes.

2. For the present an individual moving from one state to another is allowed two years in which to associate himself with the society into whose jurisdiction he has moved. In this case, however, he must keep in good standing in his old society.

3. Medical officers of the Army, of the Navy and of the Public Health and Marine-Hospital Service of the United States are not required to affiliate with a society to hold membership in the American Medical Association.

4. In the State of New York the New York State Medical Association and its branches are the only organizations recognized by the American Medical Association.

5. Any physician who is in doubt as to whether or not the society to which he belongs entitles him to membership in the American Medical Association may obtain the necessary information by writing to the secretary of his state (or territorial) association. If such society is affiliated with the state (or territorial) association, it is in affiliaton with the American Medical Association, otherwise not.

6. The requirements for membership in the American Medical Association are the same now as they have been in the past; the basic principle regarding membership, on which the Association was founded, as outlined above, is now, for the first time in many years, being enforced, and will continue to be enforced in the future.

FRANK BILLINGS, *President.*
GEORGE H. SIMMONS, *Secretary.*

The letter referred to above is as follows:

AMERICAN MEDICAL ASSOCIATION.
Office of the Secretary, 103 Dearborn Ave.

CHICAGO, Jan. 3, 1903.

DEAR DOCTOR:

Since the formation of the American Medical Association the fundamental principle has been that membership should depend on membership in an affiliated state or territorial association of the state or territory in which the individual resides, or in one of its subordinate branches. In the reorganization adopted at St. Paul, in 1901, this principle was emphasized, but not changed. For many years, however, this has not been enforced for the reason that no system of reporting or verification of membership under the old conditions was possible. The result has been that an individual might become a member of the American Medical Association while a member in good standing in an affiliated society, but later withdraw from the latter, or be dropped or expelled, and yet still remain a mem-

ber of the American Medical Association. Hence, there are members of the American Medical Association from every state and territory who do not belong to their state or territorial society, or any of its branches. The plan of organization now going into effect will prevent this anomalous condition in the future.

Meanwhile it becomes necessary to ask each one who is on the membership list of the American Medical Association and who is not a member of his state association, or of one of its subordinate branches, to unite with such by March 1, 1903. This is in accordance with the following resolutions adopted by the House of Delegates of the American Medical Association, June 16, 1902:

Resolved: 1. That the Secretary of the Association shall complete the verification of the list of members on the plan already begun, and obtain, so far as possible, correct information from the members themselves and from other sources as to the qualification of every person who now claims membership in this Association.

2. That all those who now claim membership and who are not eligible according to our laws shall be notified by the Secretary of such fact, and that they must furnish satisfactory evidence of their qualification for membership as required by our laws on or before Jan. 1, 1903.

3. That not later than March 1, 1903, the Secretary is directed, after notification, to drop from the roll of members all who are not eligible to membership in this Association.

4. That the word "local" in line 9, Section 3, Chapter I, of the By-laws, shall be construed, in this connection, to apply to the state organization, or one of its recognized branches of the state in which the person holds his legal residence.

5. That a member of this Association removing from one county or state to another may continue to hold his membership in this Association for a period not to exceed two years, without joining an affiliated society in his new place of residence; provided, however, that during this time he retains his original membership in the county or state society from which he removed.

Section 3, Chapter I, of the By-laws of the American Medical Association, referred to in Resolution 4, is as follows:

SEC. 3.—No individual who shall be under sentence of expulsion or suspension from an affiliated society (whether a directly affiliated state or territorial society or an indirectly affiliated local society) of which he may have been a member, or whose name shall have been dropped from the rolls of the same, shall be received as a member or shall be allowed to continue as a member of this Association, until he shall have been relieved from said sentence or disability by such society; nor shall any person not a member of his local affiliated medical society, provided there be such a one, be eligible to membership or be allowed to continue as a member in the American Medical Association.

This circular letter is sent to each member of the American Medical Association whose name is not found on the membership list of his state or territorial association, or any of its branches, and is an official notification, in accordance with the above resolutions, that such member's name will be stricken from the roll of members of the American Medical Association, March 1, 1903, unless by that time he shows that he is entitled to such membership.

GEORGE H. SIMMONS,
Secretary American Medical Association.

Societies.

New York Academy of Medicine, Surgical Section.—Dr. Robert T. Morris has been elected chairman, and Dr. Charles H. Peck, secretary.

Scott County (Iowa) Medical Society.—This society met at Davenport, Dec. 16, 1902, and adopted a new constitution and by-laws to conform to that suggested by the American Medical Association.

Kansas City (Mo.) Academy of Medicine.—On January 3, at the annual meeting of the academy, Dr. Charles B. Hardin was elected president; Dr. Jacob Block, vice-president; Dr. Joseph W. Sherer, secretary, and Dr. C. Lester Hall, treasurer.

Medico-Chirurgical Alumni.—The Alumni Association of the Medical Department of the Medico-Chirurgical College, Philadelphia, recently elected as president Dr. George W. Pfromm; secretary, Dr. Stillwell C. Burns, and treasurer, Dr. Emanuel S. Gans, all of Philadelphia.

Lancaster County (Neb.) Medical Society.—At the annual meeting of this society, held in Lincoln, Dec. 2, 1902, Dr. James L. Greene, Asylum, was elected president; Dr. A. L. Hoover, vice-president; Dr. H. Winnett Orr, Lincoln, secretary, and Dr. A. D. Wilkinson, Lincoln, treasurer.

Kalamazoo (Mich.) Academy of Medicine.—The annual meeting of the academy was held, January 6, at the Michigan Asylum, Kalamazoo. The following officers were elected: Dr. Herman Ostrander, Kalamazoo, president; Drs. Arthur P. Burroughs, Galesburg, and Ralph E. Balch, Kalamazoo, vice-presidents, and Dr. Delia P. Pierce, Kalamazoo, secretary.

Shiawassee County (Mich.) Medical Society.—This society held it second annual meeting at Owosso, January 6, and elected Dr. Dryden H. Lamb, Owosso, president; Dr. R. H. Scott, Laingsburg, vice-president, and Dr. Charles Shickle, Owosso, secretary-treasurer. Dr. Angus MacLean, Detroit, was the guest of honor and gave an address on appendicitis.

Marion County (W. Va.) Medical Society.—At a meeting held January 1, at Fairmont, Dr. David C. Coplin, Boothsville, was elected president; Dr. James J. Durrett, Fairmont, vice-president; Dr. James W. McDonald, Fairmont, secretary, and Dr. William H. Sands, Fairmont, treasurer. The constitution was so changed as to conform to that of the state society.

Berks County (Pa.) Medical Society.—At the annual meeting of this society in Reading, January 13, the following officers were elected: President, Dr. George Hetrich, Birdsboro; vice-presidents, Dr. James W. Keiser, Reading, and Samuel S. Hill, South Mountain; secretary, Daniel Longaker, Reading; corresponding secretary, Dr. Hiester Bucher, Reading, and treasurer, Dr. Irvin H. Hartman.

North Central Illinois Medical Society.—The twenty-ninth annual meeting of this society was held at Streator, Dec. 2, 1902. The following officers were elected: President, Dr. Jane Reid Keefer, Sterling; vice-presidents, Drs. Lucius G. Thompson Lacon and William O. Ensign, Rutland, and secretary and treasurer, Dr. George A. Dicus, Streator. The next meeting will be held in Ottawa.

Orange County (N. Y.) Medical Association.—At the regular meeting of this body at Middletown, Dec. 17, 1902, an amendment to the by-laws of the New York Medical Association was read and accepted by unanimous vote. The amendment provides that hereafter no initiation fee will be required of any one desiring membership. This will make the cost of membership in the county, state and national associations only $11, as against $16 last year.

Winona County (Minn.) Medical Society.—At the annual meeting of this society in Winona, January 6, the constitution recommended by the American Medical Association and the Minnesota State Medical Society for county organizations was adopted. Dr. George J. Tweedy, Winona, was elected president; Dr. Frederick H. Rollins, St. Charles, vice-president; Dr. James B. McGaughey, Winona, secretary, and Dr. William F. C. Heise, Winona, treasurer.

Baltimore Medical and Surgical Association.—The annual meeting of this society was held January 12. The following officers were elected for the ensuing year: President, Dr. Edward L. Whitney; vice-presidents, Drs. William P. E. Wyse, Pikesville, and Charles O'Donovan; secretary, Dr. Eugene L. Crutchfield, and treasurer, Dr. James M. Craighill. A banquet followed, at which addresses were made by the retiring president, Dr. J. I. Ingle, and the president-elect.

Minnesota State Sanitary Association.—A number of Minnesota physicians interested in sanitation and in the prevention of disease, met at St. Paul, Dec. 17, 1902, and organized this association. Dr. Henry M. Bracken, secretary of the State Board of Health, was elected president. Dr. Burnside Foster, St. Paul, in an address on "Some Problems of Preventive Medicine," advocated the establishment of a department of hygiene, and that the secretary of the department be a cabinet officer with supervision over all state and municipal health departments. The second day was devoted to tuberculosis. Dr. Henry M. Bracken opened the symposium with an address on the "Care of the Tuberculous" in which he emphasized the importance of early diagnosis, notification, and the establishment of state sanatoria. The committee on tuberculosis reported through Dr. H. Longstreet Taylor, St. Paul, which especially

condemned expectoration in public places and the maintenance of poorly-ventilated factories. Under the head of prophylaxis. Dr. Thomas S. Roberts, Minneapolis, gave kissing, and smoking infected pipes, cigars and cigarettes as leading etiologic factors. He advocated isolation of patients, legislative prevention of expectoration, and wet sweeping of streets. The following officers were elected: President, Dr. Burnside Foster, St. Paul; vice-presidents, W. B. Patton, St. Paul, and Dr. Edward D. Keyes, Winona; secretary, Dr. Emory H. Bayley, Lake City, and treasurer, Dr. J. Frank Corbett, Minneapolis.

EGYPTIAN MEDICAL CONGRESS.

First Congress held in Cairo, Egypt, Dec. 19-24, 1902.

(From our Special Correspondent.)

(Continued from page 263.)

Yellow Fever Not Propagated by Mosquitoes.

PROF. CAMILLO TERNI of the Institute of Hygiene, Messina, read a "Contribution to the Study of the Etiology of Yellow Fever." The researches around the etiology of yellow fever are at present directed with the supposition that that disease, like malaria, is propagated by a special kind of mosquito. The author has studied the question in the Hospital of St. Sebastiano in Rio Janeiro, as well as in the valley of Rio, which is justly considered as the most famous place for the yellow fever epidemics which make their appearance with more intensity every year from December to May. He comes to the conclusion that the theory recognizing the mosquito as the agent of propagation of the yellow fever has no positive foundation. He is of the opinion that yellow fever is a disease of a bacterial origin and the *Bacillus icteroides* has the major probability of being the specific agent of the infection. The author deduces his conviction especially from the fact that the organic juices as well as the gastric and intestinal contents filtered determine in animals symptoms and pathologic changes identical with those produced with the toxin of *B. icteroides*. He does not agree with Sanarelli's views, who supposes a larva as the medium, but thinks, on the contrary, that it is by the direct drinking of the infected water. The difficulty of isolation of the bacillus depends solely on the culture media, employed in warm climates to put in evidence the special characters. Using gelatin 10 per cent., exposing the cultures to a temperature ranging between 15 to 20 C., it is always possible to isolate the *Bacillus icteroides* from the vomitus as well as from the intestinal contents, and in this way a diagnosis is possible in the very initial cases which clinically are not yet definite. Exceptionally the *Bacillus icteroides* may be found in the blood, but it penetrates that fluid in the last period of the disease. It determines the malady by the toxins which it eliminates in the intestine, which toxins, when absorbed by means of the portal vein, cause the characteristic hepatic changes. Sometimes the renal changes are set up before, to which, in the gravest cases, the individual succumbs by uremia before the hepatic changes have time to take place.

Heart Diseases in Egypt.

PROF. V. DE SEMO, Alexandria, asks if heart diseases in Egypt have any special seat or particular mortalities which might differentiate them in their manifestations from those of Europe. He indicates two main divisions in valvular and arterial cardiopathies. In his practice in Alexandria he was struck by the lack of frequency of valvular vices; this would be explained by the relative rarity of acute articular rheumatism in Egypt, that great factor of endocarditis and of consecutive valvular vices. On the other hand, one observes much more arterial cardiopathies than in Europe. The author enters into the developments of the causes of arteriosclerosis; causes which are discratic, infectious, toxic, which he affirms having met in Egypt more than anywhere else. Among the discratic causes he cites the diseases which cause a slowing of the nutrition so frequent here, like diabetes, polysarcia, phosphaturia, gravel, etc., and as powerful a cause of autointoxication, the state of lessened function of the liver. Alcohol and tobacco, which are greatly abused here, the custom of over-alimentation in the truest sense of the word among the wealthy people, the overstraining and emotions proper to commercial life, furnish a great factor to arteriosclerosis. He believes that the action of tobacco is counterbalanced in Egypt by the use and abuse of coffee. He points out the extreme frequency of reflex cardiac troubles, especially of gastric and hepatic origin, and he explains it by the frequency here of gastric dyspepsia, hepatic hyperemia, etc.

The Causation of Cancer and Its Treatment Without Operation.

DR. ROBERT BELL, consulting physician to the Glasgow Hospital for Women, concerning the many theories which have been adduced to explain the causation of cancer, says there may exist a modicum of truth in such theories, but its importance only exists in the fact that in certain circumstances the influence exerted by the various conditions of life mentioned produce an effect on certain idiosyncrasies, which tend to act prejudicially on the general health. Thus they are rendered prone to any disease, cancer among the number, but the latter only when more important forces are at work.

Were cancer due either to a parasite or a microbe would we find it unilateral, and would it not be invariably accompanied by a rise of temperature, which the presence of a microbe or a parasite imbedded in the tissues would naturally produce in consequence of the amount of irritation they would excite? He is convinced that cancer, or rather the elements of cancer, are present in every individual, whether it manifests its presence or not, because he believes the cancer entity is in its original state a normal cell, which, from a combination of circumstances, has become altered in character and assumed a new rate of existence. He thinks that whatever acts prejudicially on the general health is liable to become a factor in the production of cancer, such as marriage of blood relations, bad ventilation, constipation, excess in eating or drinking, worry, sedentary habits and the neglect of important hygienic precautions. In other words, every circumstance which tends to impoverish or militate against the general health predisposes to cancer.

It is a most important fact to bear in mind that cancer is essentially a disease of civilization. It is practically unknown among savages and among those who lead a simple, and what he would designate, a natural life, so that there is no reason to doubt for a moment that it is a preventable disease. We have a palpable example of what is essentially epithelioma, existing in a harmless, or at least a passive condition, in a wart. If this excrescence is not interfered with the probability is it will remain as a disagreeable disfigurement and nothing more, but if it is subjected to rough usage instead of a passive nodule we may have arising an active epithelioma. The integrity of the epithelium depends largely on the unimpaired integrity of the thyroid. Not only are the mucous membranes and skin dependent on this organ to a large extent for the continuance of health, but, according to Charcot, Bonilly, Cuffier, Guinan and others, there is a direct physiologic relationship between the thyroid and uterus, which fact was well known to the ancients. According to Dr. F. Blumm, the function of the thyroid is to seize and render innocuous certain toxic substances which are produced in the intestine and absorbed into the blood. Such toxic substances are continually being absorbed in large quantities when constipation is persistent, especially when there has been over-indulgence in diet containing much nitrogenous material. These toxic substances prejudicially affect the functions of the thyroid and by accumulating in the blood give rise to pathologic changes of serious import. Any saccharomycetes happening to be present in the blood seize on this toxic material, transforming it into uric acid, and we have uricacidemia, which interferes seriously with cell metabolism, and in this, he maintains, we have one of the principal predisposing causes to cancer. The continuance of the entero-toxins also accounts for the cachexia which is generally coincident.

Concluding from experiments on animals, he says that in cases of cancer we should abstain from food containing much albuminous material and substitute plenty of milk. Probably the toxins which arise in milk and meat diet respectively differ in quantity rather than quality, and the possibility of neutralizing the effects of entero-toxins by administering thyroid extract is of great importance. Not only this, but we

must try in treating cancer to endeavor also to destroy the saccharomycetes, which are almost invariably present in cancerous subjects, for if their presence is permitted their effect on entero-toxins will be perpetuated; and the most potent destructive agent on them are the salicylates. At the same time, constipation, which permits of the absorption of entero-toxins, must receive our most serious attention. To put the matter in a nutshell, we must ascertain that the bowels are completely evacuated once in 24 hours, that the dietary be so modified as to be composed largely of milk food, that thyroid extract be administered in 5-grain doses three times a day, that along with this 10 to 15 grains of salicylate of soda or aspirin be given three times daily, and that the local affections be treated with a view to remove all sources of irritation, when, if the disease has not advanced too far, I am convinced it will yield to this treatment, which has frequently been the case in my hands.

He ends by giving the following as the predisposing cause to cancer:

1. Persistent and prolonged retention of feces containing an undue proportion of decomposing albuminous material, from which entero-toxins are derived, and by absorption, conveyed to the blood.

2. The blood thus contaminated produces a depraved condition of the nervous apparatus, thereby handicapping the functional activity of the various organs, interfering with cell metabolism, and eventually culminating in anemia in young persons or cachexia in the elder.

3. If the functions of the thyroid gland are at fault, these toxins, which otherwise could be neutralized, remain in a position capable of producing serious mischief.

4. If saccharomycetes be present in the blood this toxic material is liable to undergo chemical changes, resulting in the formation of uric acid, when uricacidemia will result.

5. The presence of the toxins in the blood, alone or combined, with uric acid, exert a pernicious influence on cellular structures, and confer on them a predisposition to take on a malignant metamorphosis.

6. Prolonged or repeated irritation of a part is liable to rouse into malignant activity cells which otherwise would have remained dormant.

7. The vitiated condition of the blood by prostrating the physiologic vitality of the various organs and cellular structures and paralyzing the *vis medicatrix naturæ* affords every facility for the new growth to establish its identity and increase its area at the expense of its environments.

Trachoma.

DR. VOILAS, Cairo, does not consider acute trachoma to exist; its evolution is always chronic and latent, having for its seat the cellular tissue subjacent to the conjunctiva. It is a disease of the connective tissue subconjunctival and not of the conjunctiva itself. Dr. Voilas believes in the existence of a micro-organism in trachoma which is the efficient cause of the affection.

DR. GUARINO, Cairo, has examined the conjunctivæ of some of the well-conserved Egyptian mummies, and concludes from his numerous examinations that trachoma existed from an immemorial time. He makes an anatomic study of trachoma and concludes that trachoma invades the lymphoid layers and engorges the lymphatic cells. The trachomatous bodies are isolated. They are formed of agglomerated corpuscles which represent a kind of small gland or lymphatic follicle analogous to Peyer's patches. They are glandiform neoformations covered with epithelium and scattered in the thickness of the mucosa and submucosa. It is consequently a slow infiltration in the mucosa of toxins eliminated by the various microbes which have elected their home in the conjunctival cul-de-sac. By irritating the lymphatic system, the terminal glands and the lymphatic cells these toxins provoke those productions made of neoformations which are called trachoma.

DR. ELOUI BEY, Cairo, gave a summary of the etiology and symptoms. Prophylactic measures must be taken against the dwellings and the medium in which the individual lives. The hygiene of houses, their ventilation, their disinfection even in the case of the existence of a granular patient; the cleanliness of the same and the watching about the care and medical attendance which must be given to him are the bases of the prophylactic measures which the author recognizes.

Therapeutics.

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns without allusion to inquirer.]

Arteriosclerosis.

Trunecek, in *Med. Press*, states that he has derived great benefit in the treatment of arteriosclerosis, from the use of the following combination administered subcutaneously:

℞.	Sodii sulphatis	gr. ii	13
	Sodii chloridi	gr. xv	1
	Sodii phosphatis	gr. iiss	15
	Sodii carbonatis	gr. iiss	20
	Pot. sulphatis	gr. viss	40
	Aq. destil.	ʒiiiss	105

M. Sig.: To be injected subcutaneously in the forearm.

He has used these injections, with success, in cases with pronounced changes in the aorta and other large vessels, associated with the subjective symptoms of cardiac asthma.

Professor Huchard of Paris, in the same journal, enumerates the following certain causes of arteriosclerosis: Gout, diabetes, alimentary toxins, plumbism, arthritis, chronic rheumatism, heredity and senility. And he classifies the following as doubtful causes: Alcoholism, tobacco, syphilis and mental overstrain. The treatment consists of hygiene and alimentary regimen. Milk diet should form an important part of the alimentation, while such liquids as tea, coffee and liquors of every kind should be withheld; food containing ptomains, such as fish, game, pork and tinned meat should not be advised. All liquids should be taken in moderation in order that plethora of the vascular system will not occur, which would cause arterial hypertension. Intestinal antiseptics should be prescribed. The author advises some of the following for this purpose: naphthol, benzonaphthol and charcoal. If constipation is present proper evacuants must be employed. Other medical treatment consists in employing those preparations that tend to promote vaso-dilatation. Among these he mentions nitroglycerin and sodium or potassium iodid in small doses.

As an antidyspneic and diuretic the following is of value:

℞.	Tinct. grindeliæ robustæ	ʒi	30
	Tinct. convallariæ	ʒiiss	10
	Tinct. scillæ	ʒi	4

M. Sig.: Fifteen drops three times a day in water.

Dyspnea being the principal sign of arteriosclerosis, and being of alimentary origin of a toxic nature, he institutes the following regimen for five or six months:

1. For eight days absolute milk diet, three quarts daily.

2. For the following week a mixed diet consisting of eggs, fruits, grapes, small quantity of meal each day, and never in the evening. This should be repeated every month during the remainder of the period.

3. Suppression of game, cheese, tea, alcohol, and tobacco.

4. The administration of a purgative at proper intervals.

5. During the periods of mixed diet theobromin in 10 gr. doses should be prescribed two or three times.

6. During the period of pure milk diet potassium iodid should be given.

7. In cases of cardiac insufficiency moderate doses of digitalis are recommended.

Syphilis.

The following combination is recommended by Antony as an injection in the treatment of syphilis:

℞.	Hydrarg. biniodidi	gr. iss	09
	Potassii iodidi	gr. ix	60
	Sodii phos.	gr. xv	1
	Aq. destil.		
	Normal saline sol., āā	ʒii	60

M. Fiat solutio. Sig.: Sixteen drops by hypodermic injection daily.

Gastric Ulcer.

According to an abstract in *Med. Age*, Walko has obtained good results from the use of large doses of olive oil as well as in the treatment of hyperacidity by its lessening the irritability of the gastric mucous membrane. Its value as a food is mentioned because it is absolutely non-irritating, does not interfere with the motility of the stomach and is easily assimilated. In cases of gastrectasia decomposition does not take place, and the bowels become more regular, and acts as a protective when given on an empty stomach. The pain is greatly relieved, disappearing rapidly. According to the author, a tablespoonful should be given three times a day to begin with and gradually increase the dose to one and a half ounces. In case the act of swallowing causes nausea, it may be given through a stomach tube. This treatment may be continued for four or five days until the severer symptoms have passed, excluding all other nourishment per os, although rectal feeding may be continued. This line of treatment was successfully carried in several cases.

Acne.

L. Brocq, according to an abstract in *Amer. Med.*, recommends that patients should abstain from coffee, tea, alcoholics, pork, fish, tomatoes and uncooked food, and should not eat much butter or fatty food. The following is recommended by the author, to be taken before each meal:

℞. Sodii bicarb.	gr. ivss	25
Calcined magnesiæ	gr. iii	20
Pulv. cascaræ sagradæ	gr. ii	12
Benzonaphthol	gr. ii	12

M. Ft. cachet No. i. Sig.: One such before each meal.

The areas involved should be cleansed with absorbent cotton dipped in very hot water which has been boiled, or in the following:

℞. Bran	℥iiss	10
Sodii bibor.	℥ii	8
Aq. destil.	Oii	500

M.

At night the parts may be bathed in camphor water preceded by a bath with naphthol soap. This should be followed by an ointment as follows:

℞. Beta-naphthol.	gr. ivss	25
Resorcin		
Saponis nigri, āā	gr. iii	20
Cretæ prep.	gr. viiss	50
Sulphuris prep.	gr. xxii	140
Vaselini	gr. iii	20

M. Sig.: To be applied locally.

And in the morning the following should be applied after first cleansing the parts:

℞. Sodii bibor.	℥iiss	10
Camphorated etheris sulph.	℥x	40
Aquæ rosæ	℥iiiss	105
Aq. destil.	℥v	150

M. Sig.: Apply locally.

Calcium Salts.

Boigey, in *Amer. Med.*, states that he has derived good results from the use of large doses of lime salts in the treatment of diabetes. Injections by hypodermoclysis of the glycerophosphate of calcium were employed, injecting 25 centigrams each time. This preparation was also given by the mouth in 2-gram doses. Great diminution in the amount of sugar eliminated was observed. According to the same periodical A. Bonelli has treated epilepsy by various preparations of calcium. Lime water, calcium carbonate, calcium bromid or the lactophosphate was used. In practically every case the administration of some one of these preparations was followed by a diminution in the severity and frequency of the attacks. In the experience of the author, these preparations show greater efficiency given by hypodermic injection than when given by the mouth. The injection is given in doses of 1 per cent. solution, the daily dose of the calcium chlorid ranging from 1/3 to 1 grain (.02-.06). A 1 to 30 solution of the calcium lactophosphate may be substituted in doses of 5 to 10 grains (.30-.60) daily. The number of the seizures are decidedly decreased in number.

Acute Bronchitis.

As an expectorant in acute bronchitis the following combination is useful:

℞. Syr. scillæ	℥i	30
Ext. lobeliæ flu.	℥i	4
Tinct. opii	℥iiss	10
Ext. ipecac. flu.	gtt. xv	1
Syr. pruni virg.	℥iss	45
Syr. picis liq., q. s. ad	℥iv	120

M. Sig.: One teaspoonful in water four times a day.

Sulphur for Dandruff.

The following combination is recommended by G. T. Jackson in *Trans. Amer. Dermat. Assoc.*:

℞. Sodii boratis	gr. xv	1
Sulphuris precip.	℥iiiss	14
Ung. aq. rosæ	℥i	30
Ceræ albæ	℥iiiss	14
Petrolati	℥iiss	45

M. Fiat unguentum. Sig.: Apply locally once or twice a week.

The above does not have the odor of sulphur and does not render the hair too greasy, and at the same time checks the dandruff.

Method of Taking Castor Oil.

A simple method of taking castor oil, according to *Med. News*, without producing any nauseating effects, is to instruct the patient to wash out the mouth with water as hot as can be borne, and then swallow the oil, and follow this by rinsing out the mouth well with hot water. The first swallow of the water cleanses the mouth, makes the membranes hot, so that the oil does not stick and consequently slips down easily.

Affections of the Cornea.

The following is recommended by Fédorow in *Westnik Ophthal.* in conditions causing infiltrations of the cornea:

℞. Ichthyol.	gr. iss	10
Cocainæ hydrochlor.	gr. iiss	15
Vaselini	gr. lxxv	5

M. Fiat unguentum. Sig.: Apply locally to the cornea.

Ergot in Chronic Bronchitis.

A. Martinet, according to *N. Y. Med. Jour.*, recommends ergot in certain forms of chronic bronchitis where the pulmonary catarrh is of long standing, etc. The combination used is as follows:

℞. Ext. hyoscyami	gr. 1/6	01
Quininæ sulph.	gr. 3/4	05
Ergotin	gr. iss	09

M. Fiat pil. No. i. Sig.: One to be taken every two hours through the day, or six in the twenty-four hours.

M. Renaut recommends the use of the balsams, such as terpin, syrup of Canada balsam, or syrup of tolu, alternating with ergot, which may be combined with opium and hyoscyamus as follows:

℞. Ext. hyoscyami	gr. 1/6	01
Pulv. opii	gr. iss	09
Ergotin	gr. ivss	25
Cacao butter, q. s.		

M. Ft. suppos. No. i. Sig.: To be used as a suppository.

Or for five days in the week he recommends the following:

℞. Ext. hyoscyami	gr. 1/6	01
Terpin	gr. iss	09
Ergotin	gr. 3/4	05

M. Ft. pil. No. i.

Sig.: Two such pills at a dose, three times a day with hot water containing syrup of Tolu.

And the following is advised in chronic bronchitis, accompanying la grippe:

℞. Strych. sulph.	gr. 1/60	001
Ergotin	gr. 3/4	05
Quininæ sulph.	gr. iss	10

M. Ft. pil. No. i. Sig.: One every two hours, except at night, or from six to eight in the twenty-four hours, to be taken in an infusion of hot sugar, water and syrup of Tolu and a teaspoonful of cognac.

Medicolegal.

Refusal of a Parent to Allow a Child Medicine.—Section 708 of the Penal Code of Georgia declares that "whoever shall torture, torment, deprive of necessary sustenance, mutilate, cruelly, unreasonably and maliciously beat or illtreat any child," etc., shall be guilty of a misdemeanor. The theory under which the accused was prosecuted, in what is now entitled the case of Justice vs. State, was that he was guilty of depriving his minor child of necessary sustenance, because, on account of a religious belief, he refused to procure medicine to be administered to any of his children when they were sick. It was not shown or attempted to be shown that the accused deprived his minor child of food. The specific allegation was that the accused, Sion Justice, did "unlawfully deprive of necessary sustenance one William Jordan Justice, a child five and a half years old; the said William Jordan Justice being ill, and the said Sion Justice failing and refusing to provide said child with necessary sustenance, the said Sion Justice being the father of said child." The trial resulted in a verdict of guilty. But the Supreme Court of Georgia reverses the judgment of the trial court, holding that evidence that a father refused to permit medicine to be administered to one of his minor children while sick does not support a conviction of the father for depriving such child of necessary sustenance, within the meaning of the above statute, which declares such deprivation to be an offense against the laws of the state. In the opinion of the Supreme Court, there is a very great difference between depriving a child of sustenance and refusing to permit medicine to be administered to him. Sustenance, it says, is "that which supports life; food, victuals, provisions"; while medicine is defined to be "any substance administered in the treatment of diseases; a remedial agent; a remedy; physic." The statute quoted, in the use of the word "sustenance," means that necessary food and drink which is sufficient to support life and maintain health. And evidence that, while a father fully provides for the wants of his children as to food, he refuses to permit them to take medicine, will not support a conviction under this statute. Nor does the Supreme Court know of any provision in the penal laws of the state enacted to meet a case of this character. It appears from the evidence, the Supreme Court goes on to say, that, under a belief characterized as a religious belief, the father conscientiously prohibits the use of any kind of medicine by any member of his family. From the standpoint which a majority of us occupy, this is a grave and serious error of judgment, and oftentimes would deprive those who are nearest and dearest to us of the means of alleviating pain and suffering.

Company's Liability—Surgeon's Duty—Second Operation.—The Supreme Court of Washington holds, in the case of Sawdey vs. the Spokane Falls & Northern Railway Company, that, if the company did contract, for a consideration, to treat its employes for any injury they might receive while in its employ, it was liable for the malpractice of the surgeon employed to treat the party suing. The company contended that it had undertaken to treat him gratuitously, and was liable only for failure to use ordinary care in selecting the surgeon, resting this contention first of all on the fact that he was injured after he had ceased his work for the day. But the court points out, among other things, that there was evidence tending to show that the company had never made it known that it claimed that its contract was only to treat its employes for injuries received by them in the course of their employment. It had always, so far as shown, acted to the contrary. It took the party suing to its hospital and entered on his treatment without informing him that its contract was limited, or that it claimed to be treating him gratuitously. Clearly, it ought not to be heard now to say, in order to escape liability for malpractice, that it was only extending to him a charity. Moreover, as all the surplus over and above the cost of treating its employes, derived from deductions from their wages, inured to its benefit, and it recognized no responsibility to account for it to any one, there was in this case both the element of contract and profit. The original injury was an oblique fracture in the lower third of the femur. To secure the result finally obtained the injured party was obliged to submit to a second operation, with its accompanying dangers, delay in recovery and consequent pain and suffering. This was claimed as an element of damage in the complaint; and, the court says, if it was made necessary by the maltreatment of the surgeon first in charge, it could be recovered for, no matter how successful the final operation was. The contract implied by law from the mere employment of a surgeon is that he will treat the injury he is employed to treat with ordinary diligence and skill. This requires that he bring to its treatment such a degree of skill and diligence as surgeons practicing in the same general neighborhood, in the same line of practice, ordinarily have and exercise in like cases. He must not experiment in his treatment of the injury. On the contrary, if he desires to avoid liability for his mistakes, he must treat it in some method recognized and approved by his profession as most likely to produce favorable results. If there be more than one of these applicable to the particular case in hand, he is not, of course, liable for an honest mistake of judgment in his selection of the method; but if bad results follow, and liability therefor is to be avoided, it must appear that the treatment applied was approved and recognized, as well as that it was pursued with ordinary diligence and skill. The fact that a second operation was necessary in this case to obtain the results finally obtained was some evidence that the original attempt was not performed with that degree of skill which a surgeon ordinarily brings to the treatment of such an injury. But the court thinks it well to say that the company did not, by its contract, undertake to effect a cure of the party's injury or restore his broken limb to its normal condition. It was in no wise responsible for the original injury, and it undertook only to bring to its treatment that ordinary diligence and skill which surgeons usually exercise in similar cases; and, if it did this, it was not responsible for the results. But if it did not so treat it, it was responsible only for the injury its failure to do so entailed.

1 *Drainage in Chronic Intestinal Catarrh: Its Importance and Technic. Norman Bridge.
2 *Diphtheria Antitoxin in the Infectious or Bacterial Bronchopneumonia of Childhood. Joseph O'Malley.
3 *The Etiology of Endocarditis, with Special Reference to Bacterial Agencies. Sanford Blum.
4 Therapy of Otitis Media Suppurativa Chronica. Lee Wallace Dean.
5 The Lorenz Operation, with Report of a Case. James K. Young.
6 A Contribution to Pernicious Anemia. O. E. Lademann.
7 A Comparison between Foreign and American Surgery. Nicholas Senn.

1. **Intestinal Catarrh.**—Bridge notes the importance of keeping the colon free from accumulations in this condition and that regular complete and harmless evacuations are more useful than any other measure in the prevention or treatment of chronic catarrh of the colon. It ought to be a cardinal doctrine that no other treatment is in order until these regular evacuations are provided for, that is, until free drainage is instituted. The evidences of accumulations are numerous in practice and produce uncomfortable symptoms, insomnia, general discomfort in the abdomen or back, nervous disturbance, diarrhea, etc. The obstacles may be enteroptosis, rigidity of the colon at times and the vertical posture of the body which prevents easy evacuation. The means to accomplish drainage should be employed regularly and not merely as the patient feels like it. Mild laxatives, cascara and salines, according as they agree best with the patient, psychic methods, enemas properly and regularly taken, best plain water or normal salt solution. Bridge also mentions the effect of position in giving the enema as assisting in its effectiveness. An abdominal bandage may be of some use in preventing enteroptosis and chilling or cold taking. The best form of bandage is one made of elastic material and to fit firmly about the lower part of the abdomen. All its good effects depend on its being kept in the

right position, making steady and firm pressure. If it exerts its chief force on the upper part of the abdomen it can do more harm than good, by aggravating the splanchnoptosis.

2. **Diphtheria Antitoxin in Bronchopneumonia.**—O'Malley has employed antidiphtheria serum in bronchopneumonia with excellent results, and reports three cases. He thinks we have in it a most valuable therapeutic agent for a class of cases otherwise beyond therapeutic aid, especially those cases of bronchopneumonia which so often cause a fatal complication in the bacterial diseases of childhood, such as measles, influenza, whooping cough and scarlet fever.

3. **Endocarditis.**—After a historical sketch, Blum reports a case of his own observation which he thinks is the only one of positive bacterial endocarditis reported in an infant, as well as the single known case of pyocyaneous endocarditis in which a mixed infection did not exist. He sums up that bacterial agencies are active in the causation of endocarditis, that their presence in the circulation is not alone a sufficient cause, there must be a predisposition, a place of least resistance, for it to secure a foothold.

9 *Two Cases of Perforation in Typhoid Fever, in One of Which an Operation Was Performed. James Hendrie Lloyd and Thomas L. Coley.
10 *Two Erroneous Surgical Decisions in Intestinal Perforation from Typhoid Fever. John B. Roberts.
11 A New Method of Hemo-alkalimetry and a new Hemo-alkalimeter. Arthur Dare.

8. **Syphilis.**—Renaut holds that syphilis is an infectious disease, all the stages of which are characterized by an attack on the blood vessels, especially affecting the intima. First a multitude of arterioles are affected as is seen in the roseola, in the skin. Deeper lesions follow, but these are slight. Its action then becomes localized to territories corresponding to the important arterial branches. The lesions are then better circumscribed and have more serious consequences. This endarteritis produces in the tissues a process of sclerosis lasting as long as the endarteritis does. This, generally considered, is the histopathologic character of syphilis. Nothing, however, authorizes the statement, he thinks, that sclerosis, once formed, becomes independent of the syphilis or remains unchanged; it is by no means incurable.

9 and 10. **Typhoid Perforation.**—The two cases reported by Lloyd and Coley illustrate, they think, the difficulties of determining the onset of perforation in the course of enteric fever. Roberts, whose diagnosis was unfavorable to operation, also points out the difficulties and discusses the cases.

16 *Topical Blood-letting as a Derivative and Revulsive Remedy in Congested and Inflamed Hemorrhoidal Blood Vessels and Tumors and in Other Affections. William Bodenhamer.

12. **Chemical Pathology.**—McCaskey's article deals with the subjects of immunity, etc.

13. **Uterine Displacements.**—Ferguson describes the operation of anterior fixation of the round ligaments, as he performs it, as follows:

Place the patient in the Trendelenburg position. Make a median incision about three inches in length through the abdominal wall, the lower angle of which reaches the suprapubic fold, and dissect the fat and skin from the anterior sheath of the rectus muscle on either side of the abdominal incision, corresponding to its lower third. Pass two fingers of the left hand into the abdominal cavity on one side beneath the rectus muscle, already exposed anteriorly, to locate and protect the bladder; then make a stab wound through the rectus muscle in the direction of its fibers into the abdominal cavity, between the two fingers, an inch from the median incision and an inch and a half from the pubic bone. Before withdrawing the knife, pass an artery forceps alongside of it into the peritoneal cavity, and with it seize hold of the round ligament and a portion of the broad ligament beneath it, near the uterus. Now insert the suture which is to prevent bowel from slipping between the uterus and bladder, or, for the same purpose, suture the round ligament to the parietal peritonæum, as already mentioned. Then drag the proximal end of the round ligament through the rectus muscle with the forceps already attached to it, and sew it and the subjacent portion of broad ligament to the anterior sheath of the rectus muscle, leaving a stump about half an inch long between the parietal peritonæum and uterus.

It must be remembered that the round ligament is a part of the broad ligament, and in this operation it is not separated from it.

Deal with the other side in a similar manner, close the abdomen, and the operation is complete.

In suturing the peritoneum care must be taken not to leave any raw surfaces that may render adhesion of the viscera to the abdominal scar possible. This can be avoided by everting the cut edges of the peritoneum and sewing the normal peritoneum to the normal peritoneum behind the raw edges by a continuous suture of catgut. This operation is applicable to various displacements, anterior, posterior, anterior and posterior lateral and for prolapse, as well as for flexures affecting the patient's health and resisting treatment. It is also applicable when the abdomen is opened for other purposes and the uterus is displaced. The advantages claimed are easy performance, all the structures being visible, the uterus being left free in the abdominal cavity as no stitches or bands are attached to it. There is no interference with the physiologic functions of the organ, and it has a wider range of application than any operation known to him. The article is profusely illustrated.

14. **Intestinal Indigestion.**—Weber reports three cases which, he thinks, illustrate the connection between arteriosclerosis and nephritis and intestinal indigestion. He speaks particularly of the method of treatment adopted by him, the use of small doses of iodid of potash for arterial and renal sclerosis. He is convinced that the iodids given in relatively small doses three times daily, continued for months, and even years in this way, have the power to retard, modify and improve the subacute and chronic inflammatory processes in the connective tissue of parenchymatous organs like the kidneys, liver and lungs, and especially sclerotic disease of the arterial vessels. This, he thinks, is brought about by direct inhibition of the proliferation of the connective tissue and subsequent induction of disintegration and fatty metamorphosis of infiltrated corpuscular elements and the removal of the same. It is reasonable to assume that the drug acts through the lymph channels by direct action on the irritating substances, by stimulating the vasomotor nerves and increasing functional activity. The favorable influence of the iodids can be clinically demonstrated and is more decided in arterial sclerosis than in similar diseases of the parenchymatous organs. With a syphilitic history it is wise to give larger doses for awhile.

15. **Flat Foot.**—The causation of flat foot is given by Thompson as in rheumatic or gouty affections of the lower extremities in the majority of cases. Flat foot is frequently observed where there is swelling or edema, especially of the feet and ankles, and in all probability macreation of the tissues causing stretching or weakness of the structures. This form is particularly painful and characterized by sharp muscular spasm and constant pain of the foot and legs, more marked after rest, and especially on rising in the morning. In rickets the flattening of the arches is due to the laxity of the ligaments and tendons, and is also produced by knock-knees, which cause also a mechanical valgus. This form is usually not painful. Paralyses cause flat foot when they affect the calf or anterior leg muscles, by permitting stretching of the tendons and muscles and causing lack of support to the arch. The contraction of the opposing muscles aggravates the condition. This variety is also usually not painful. General muscular weakness causes simple flat foot by stretching of the tendons and is usually non-painful. Traumatism may be either direct or indirect. There may be tearing of ligaments, breaking down the arch, causing an exceedingly painful form of flat foot. Indirect traumatism includes cases which are caused by overweight and long standing. There is usually more or less pain with this form. There are also varieties due to disease or injury of the adjacent parts, such as tuberculous ankle-joint disease, tumors, Pott's fracture, etc. He describes the anatomy of the arch of the foot and the symptoms of the disease. The treatment is essentially mechanical. Mild cases can be relieved by adhesive plaster straps. The mechanism of reduction is described by him as follows:

Grasp the foot firmly and extend it sharply on the tarsus (this increases the space between the internal cuneiform and the astragalus). Then forcibly invert and adduct the foot and flex it again to 90 degrees, maintaining the adducted and inverted position. This will bring the scaphoid back into place and re-establish the relations of the arch. With the foot held in this position adhesive plaster straps are applied firmly, by attaching one end over the instep and bringing the other end over the outer side of the foot, under the sole, and upon the inner side of the foot, crossing over in front of the ankle joint and up around the calf in a spiral manner to just below the knee. A second, third and fourth strap are applied in the same manner. Short straps may be applied anteroposteriorly around the heel, crossing at the instep to hold the foot more firmly, but these are not essential. Plaster of Paris is applied in aggravated cases (in which an anæsthetic is used) in the same manner and after the same method of reduction. This dressing holds the foot in *varus*, or inversion. The adhesive plaster straps must, of course, be a temporary dressing or be renewed frequently. They are usually employed while steel insoles or braces are being made. I should like to call attention to the fact that ready-made insoles are impracticable, because each case differs from every other in the character of the deformity; therefore a plaster cast should be made of each foot, and cut out to correct the deformity, and the insole must be fitted to this cast.

Insoles, he says, are used in milder cases and should be worn for a long time until the arches are restored to their normal condition. He describes the forms of braces and suggests the proper use of the foot to prevent flat foot, educating the patient to use the heel and toe method in walking, the foot parallel rather than on diverging lines, in running or jumping to catch the weight on the front of the foot rather than on the heel. This point, with the added one of careful attention to "running over of the heels" will do much toward prevention. He also advises against the use of rubber overshoes, patent leather or enamel shoes or any waterproof footwear.

16. **Topical Blood Letting.**—Bodenhamer pleads for the use of small local blood letting and leeches as a partial substitute for venesection, in case of inflamed hemorrhoids, tumors, etc.

17. **The Boston Floating Hospital.**—The methods of treating infants in the Boston Floating Hospital are described by Hastings, and some points especially noted. It was found that fresh, clean milk is better for babies than the older pasteurized or sterilized food. The sort of milk required was obtained from the Walker-Gordon dairy. Whey was not largely used, but probably may be, and the hospital authorities believe that the whey for sick babies should be made with essence of pepsin and whole milk, not skimmed. Most babies with gastrointestinal trouble were started on rice water, and it was found that they could be fed for two weeks on nothing else, and only lose one-half an ounce in weight. If there was a history of vomiting they were often started on the well-known albumin water or Jacobi's modification. For real exhaustion they used panopepton or beef juice and manufactured it themselves. In the diarrheal troubles of babies and some of the infections, the author insists on the importance of keeping flies away from them and the dejecta, and frequent cleansing of the hands and forearms of doctors and nurses with a solution of cyanid of mercury. Nearly all the very severe cases were treated with alcohol, and another means of stimulation was hyperdermoclysis with normal salt solution. Enteroclysis or irrigation of the lower bowel was performed nearly seven hundred times. The opinion, however, is growing that cases for this treatment should be carefully selected. They tried the lime water and creolin solution, the only one which seemed to have any special value. For persistent vomiting nothing proved better than lavage, using two pints of normal salt solution. A few drugs were tested. The fat-free tincture of digitalis was used in thirty-one cases with good effect. Tannalbin in doses of 5 to 10 grains every two to four hours was found to check bloody movements, which did not yield to any other treatment. Two or three relatively sure signs of approaching death were noted. one was brown vomitus, not containing blood or reacting to the hemin test. Another was the appearance of purpuric spots or streaks on the abdomen. A third fatal sign is a drop of the temperature to 95 F. or thereabouts. There was no great difficulty in getting the temperature back to normal, but the babies died just the same. The postmortems showed that nearly every case of severe bowel trouble was, pathologically, acute follicular ileocolitis, with very marked thickening of the lower bowel, swelling of the follicles and often some ulceration, and fatty degeneration of the liver. One case was met which justified the clinical term, gastroenteritis, all inflammation being in the stomach and upper duodenum. The heart muscle was usually not much affected, nor were the kidneys seriously involved.

19. **Vesical Appearances in Renal Suppuration.**—Garceau reports a case which he thinks is of interest, showing that a suppurating kidney may exist and the corresponding ureteral eminence not be at all diseased. That long-continued boracic acid vesical injections will, and do, reduce the intensity of the cystitis to almost nothing. The diagnosis of a suppurating kidney in all cases must be made by seeing purulent urine exuding from the corresponding ureteral orifice. So far as the lesions at that point being a positive sign, their absence is not conclusive that suppuration does not exist.

20. **Hay Fever.**—The preventive treatment of this condition consists in local and general measures, the former consisting in correction of abnormalities and cauterizing the mucosa that is likely to be most susceptible, while the general treatment must be directed to an increase in elimination and decrease in production of uric acid, to the correction of existing neuroses and the removal of constitutional or local abnormalities. Lockard finds three factors in the production of the disease: 1, neuroses; 2, some lesion or hypersensitive condition of the nasal membrane; 3, the inhalation of pollen or certain odors. He has tried the fluid extract of solidago and ambrosia in two or three cases with benefit in two. The remedy advised and used by Curtis being a secret one, it was not available. He considers adrenalin a remedy of great power for the nasal discomfort. In all cases he administers nitro-muriatic acid (not the dilute), three to five drops after meals and before retiring. The acid is almost a specific; in the great majority relief is almost immediate.

27 A Case of Sepsis Following an Attack of Osteomyelitis from a Slight Cause. Samuel Kohn.

23. **Heredity.**—Smith discusses the heredity of tuberculosis, admitting that, as a rule, it does not exist, but pointing out one or two obscure points which increase the difficulty in its estimation. Nearly everybody, moreover, has had some tuberculous ancestors. Gout and rheumatism are also discussed, and he notes the fact that in gouty cases there are liable to be direct exciting causes as well as more hereditary ones. The apprehension that many people feel, who have lost ancestors from cancer, that they will develop the disease seems to have some foundation in fact. Bronchial asthma is another disease in which we often find a parent or grandparent affected. In certain families there is a physical tendency to cardiac disease. Probably the same is true of renal troubles. Arteriosclerosis is another condition which has been of late years looked on as showing distinct hereditary tendencies, and he mentions also hemophilia as an instance of heredity. The relation of heredity to disorders and diseases of the nervous system is a very intricate as well as interesting subject. He does not go into it at any length, however, though he says that mental disease, perhaps more than any other, is hereditary. The alcohol habit may also be hereditary, either through deficient mental control or through special sensitiveness to the effect of the stimulant. In conclusion he mentions the tolerance which may be more or less influenced by heredity. Some persons do not succumb as readily as others to disease, being able to tolerate the condition for a much longer period. He mentions, also, racial peculiar-

ities, such as the resistance to tuberculosis by the Jews and their special liability to neuroses, diabetes, etc.

25. **Puerperal Eclampsia.**—The importance of getting the morbid matters out of the blood in threatened eclampsia is insisted on by Stewart, who believes in venesection in these cases to a certain extent at least. Frequent small blood-letting is not depressing, but removes a depressing poison and stimulates the blood-making organs. If convulsions have already taken place, his treatment differs a little from the ordinary. He uses carbonic acid gas in a vaginal capsule in the cul-de-sac—grs. x sodæ bicarb. and grs. v acid tartaric—which seems to soften the cervix and relieve dilating pains, repeating it every two hours or oftener, following an hour after insertion with a heaping teaspoonful of sodium bicarbonate and an even teaspoonful of lysol to a quart of water at 106 for a douche. When the cervix is large enough he uses a rubber bag dilator, hanging the artery forceps or a light weight to the stem. A light constant pull aids very much. When dilatation is complete and the pains are not strong, he then ruptures the membranes. He finds the introduction of forceps and leaving them alone for from one-quarter to a half-hour often very effective. As regards venesection, he says that the pulse is a guide to quantity and age to advisability. No case of early albuminuria in a robust woman should be allowed to pass the fifth month of pregnancy.

33 *Complications of Chronic Suppuration of the Middle Ear. Robert Lewis, Jr.
34 *The Treatment of Chronic Suppuration of the Middle Ear. James F. McKernon.

28. **The Medical Inspection of Schools.**—Somers' article obtained the second prize given by the Maltine Company. It is to be concluded.

29. **Acute Middle-Ear Suppuration.**—The predisposing causes are anything which conduces to chronic congestion of the upper air tract and tympanum. The general predisposing cause which without any lesion may render it susceptible to infection, may be any constitutional condition that lowers the vitality of the system. The middle ear is most commonly infected through the Eustachian tube, but it is not proven that the mere presence alone of infective germs is sufficient to cause disease. One of the most common etiologic factors is direct introduction by insufflation of water through the nares. This most commonly occurs as an accident during bathing, but may be induced by methods of treatment. Purulent inflammation involves always the upper portion of the tympanic cavity in contradistinction to acute catarrhal inflammation which is limited to the lower portion. Dench mentions the symptoms and remarks that the most important one in infants is a sudden increase in the temperature which may go up to 105 or 106. If such a change is observed without any apparent cause, a careful examination of the ear is suggested.

30. **Complications of Acute Middle-Ear Suppuration.**—The complications mentioned by Clemens were mastoid periostitis, inflammation of the mastoid cells, destruction of the soft parts, adenitis of the cervical and post-auricular glands, retropharyngeal abscess, intracranial inflammation, meningitis, cystitis, etc. In all the obscure diseases of children repeated and careful ear examination should never be neglected.

31. **Treatment of Acute Middle-Ear Suppuration.**—There are certain conditions which predispose to middle-ear disease: 1, the presence of adenoid tissue in the pharynx. Adenoid patients have running ears in a far larger proportion of cases than others. The ear complications of la grippe can generally be prevented by careful treatment of the nose at the very commencement and cleansing with detergent sprays; anything which renders the tissues clean and free from secretion. The patients should be cautioned to avoid violent blowing of the nose. Phillips says practitioners do not, as a rule, do enough to prevent such suppuration. If there is pain before the establishment of a discharge, the use of heat and narcotics should be relied on: hot water irrigations at a temperature of 100 to 110 and some form of anodyne internally. If the tympanic membrane is bulging and giving evidence of pus, a free incision should be made. It should be carried not only through the membrane proper, but upward through the attic region and well out on to the wall of the canal under strict antisepsis. It should be a routine procedure to make a microscopic examination of the pus as the nature of the micro-organism has an important bearing on the complications. He favors prompt operation in cases of early symptoms of mastoid involvement. The conclusions are given as follows:

1. In acute middle-ear suppuration early and free drainage is of the utmost importance; 2, patients should remain in bed until acute symptoms have passed; 3, free purgation (preferably by means of calomel) should be resorted to; 4, microscopical examinations of pus should be made; 5, local treatment should consist of cleanliness and free drainage; 6, proper internal medication should not be ignored; 7, prolonged attempts to abort suppuration of the mastoid cells are to be condemned; 8, early operative interference in mastoid suppuration prevents the more serious complications and gives far better hearing results; 9, uncomplicated cases of acute suppuration of the middle ear, when properly treated, always recover in from two days to three weeks; 10, the responsibility for preventive treatment must be largely assumed by the family practitioner. He should fully appreciate the importance of preventive treatment when caring for grippe, the exanthemata, or other infectious intranasal conditions, and also, the early and complete removal of diseased adenoid tissue.

32. **Chronic Purulent Otitis Media.**—The causes, symptoms and pathology of chronic otitis media are described by Ledermann, who emphasizes the danger of chronic discharging ears.

33. **Complications of Chronic Otitis Media.**—Lewis first notices the local changes at the spot, bone necrosis, cholesteatoma, mastoiditis, polypi, etc., and later brain involvement, pachymeningitis, and general septicemia which may occur from disintegration of a thrombus. The vascular system and the lymphatics may both be routes of infection. The insidious advance of the disease is remarked. Brain abscesses have often been found to be the cause of death when no such lesion was suspected.

34. **Treatment of Chronic Middle-Ear Suppuration.**—McKernon describes the dry and wet treatment, the latter being the one ordinarily used, consisting in syringing the ear with bichlorid of mercury at 1 to 4,000 or 1 to 8,000; boric acid, 20 grains to the ounce of boiled water, carbolic acid solution of 1 or 2 per cent. strength, formalin or potassium permanganate. Normal saline solution or warm sterile water is all that is necessary in many cases. After the parts are cleansed he mentions the following as a good solution to further sterilize the parts, namely, equal parts of 1 to 1,000 bichlorid of mercury solution and absolute alcohol to which may be added 10 to 20 grains to the fluid ounce of boric acid. If granulations are present they may be destroyed by chemical agents, nitrate of silver or chromic acid. The parts to be cauterized should be cocainized to avoid pain. An alcohol, boric acid and bichlorid solution can be used at home by the patient after the discharge becomes less abundant, five to eight drops being placed in the ear morning and evening after the cavity has been cleansed. If perforation of the drum is on a level or higher than the short process of the malleus, with a small amount of thin serous secretion, thorough cleansing of the middle-ear by means of a middle-ear syringe, is indicated, injecting the sterile solution through the perforation until the cavity is cleansed, and then using an astringent solution of nitrate of silver, not stronger than 5 grains to the ounce. A preliminary solution of eucain or cocain will make it more comfortable. Stronger solutions may be used later, if required. Zinc chlorid has been employed as well as protargol. If the perforation in the drum is large he would not hesitate to use peroxid of hydrogen, but would prefer hydrozone. In case of very persistent discharge, with an area of exposed bone complicating a simpler condition, he has found carbolic acid of great value. The head is placed in a horizontal position and the canal partially filled with pure carbolic acid, allowed to remain about thirty seconds and then the canal syringed with pure alcohol. The complications

of mastoiditis, facial paralysis, etc., are mentioned in conclusion.

41 Recent Discoveries in the Domain of Etiology. D. H. Bergey.
42 Some Epidemics of Typhoid Fever Caused by Infected Water and Milk. I. C. Gable.

37. **State Board Examinations.**—Kelly criticises the questions of state board examinations while not depreciating their value to the profession in raising the standard of medical education, getting rid of bogus colleges, etc. He thinks there is still room for reform, that examinations should not be confined to merely written methods, but should be made practical. The candidate should be made to diagnose, and even operate and perform certain laboratory diagnostic work, etc. He thinks that reciprocity is a thing that ought to come and should be facilitated.

38. **Pericarditis and Bright's Disease.**—The occurrence of pericarditis in connection with Bright's disease has been noted by early observers, and since Taylor's publication in 1845 the importance of the complication has been realized. Allyn reviews the literature and theories and reports cases. The symptomatology differs from that of other forms, occurring as it does in the final stage of a disease, which can itself account for all the symptoms that may be present. It may be absolutely latent and painless to the end, and in many instances is only detected at autopsy. He calls attention to four distinct signs which are important: 1. Dulness in the first interspace to the right of the sternum, which has been present in every case that he has examined. 2. Fluoroscopic examination, which is very important. 3. Exploratory puncture, which he holds harmless if carried out with due aseptic precautions. 4. Pulsation of the vessels of the neck. The prognosis is practically always fatal; it only hastens an otherwise inevitable ending.

39. **Nephritis in Smallpox.**—From a study of 1,088 urinary examinations in 128 cases of smallpox, Welch and Schamberg find that albuminuria is more frequent in smallpox than is generally believed, being present in 65 per cent. of the cases examined. Tube casts were found in 45 per cent., warranting the assertion that albuminuria is the expression of structural change. In their experience mild and discrete cases have been accompanied by nephritis almost as often as cases with more profuse eruptions, suggesting the influence of smallpox poison in the kidney involvement. Repeated examinations are necessary to avoid misleading results. The clinical symptoms of variolous nephritis are usually mild and not as obvious as those of scarlatinal cases. Albumin may persist in the urine in minute quantities after convalescence and histologic examination of the kidneys indicates that this represents interstitial changes in the kidney. If it is true that the albuminuria accompanying infectious diseases is, in large part, the expression of a structural change in the kidneys, is it not probable that the damage thus done may, if unrecognized and uncared for, insidiously eventuate in chronic Bright's disease? The urine of patients convalescent from infectious disease should be carefully and repeatedly examined and measures taken accordingly.

44 Contribution on Otogenous Disease of the Brain, Meninges and Venous Sinuses. Dr. Sturm and Dr. Suckstorff.
45 *The Use of the Rotatory Bur in the Treatment of Chronic Suppuration of the Middle Ear. Dr. Sturm.
46 *Vertigo. Rudolph Panse.

45. **The Rotary Bur.**—The use of the bur to smooth the bony cavity after radical mastoid operations, as suggested by Körner, is not as harmless as it appears. Heat generation may cause necrosis, and Körner and other former advocates have abandoned its use in dressing the bone in radical operations. Although still in use, its indications are limited, as when it becomes necessary in radical operation to open the vestibule or semicircular canals and in chronic cases where the pus production is limited to the attic and where removal of the ossicles fails to relieve the otorrhea. The lateral wall of the attic can readily be removed with the bur, thereby exposing the attic with its contents. It is also used in those cases where superficial necrotic areas of the bone are present on the inner wall or the floor of the tympanic cavity. The bur removes the necrosed tissue and the bone returns to its normal smooth condition. To avoid injury from heat it is well to stop the bur every few seconds, the interval being employed in mopping away blood. The bur used has a much slower action at the pole than at the equator, enabling the operator to proceed more cautiously when using the pole and to work faster while entering the attic, where the coarser part of the bur comes into play when working laterally. General anesthesia is dispensed with unless the attic is to be opened when it is required, but not in removing necrosed tissue. He reports cases of its use and speaks of the advantages of the method.

47 *The Relations between the Lymphatics and the Connective Tissue. W. G. MacCallum.
48 *The Accuracy of Certain Clinical Methods. Charles P. Emerson.
49 *Albuminous Expectoration Following Thoracentesis, with Report of a Case. Herbert W. Allen.
50 A Study of the Reticular Supporting Network in Malignant Neoplasms. Paul G. Woolley.

47. **Lymphatics and the Connective Tissue.**—From his study of the development of the lymphatics, MacCallum finds that the walls, though delicate and easily ruptured, have still a complete endothelial lining throughout, in appearance analogous to that of the blood vessels, and that the processes of their growth seem to be in every respect similar to those of the blood vessels, with the exception, perhaps, of the lack of considerable distending pressure.

48. **Certain Clinical Methods.**—Emerson has tested a number of clinical diagnostic methods, with special reference to their accuracy and availability, using several independent observations by different persons with the same instrument on the same case, and at the same time as far as possible. He does not recommend the Oliver hemocytometer for clinical work, but finds the hematocrit useful in determining the presence of lipemia, cholemia, hemoglobinemia, but not for counting the cells. The Thoma-Zeiss apparatus requires experience and practice. Expertness with it is readily lost, but otherwise it seems to be satisfactory. Of the hemoglobinometers, he speaks well of Miescher's modification of the Fleischl and of Gower's instrument when it is well made. The Dare instrument is a new hemoglobinometer, which promises to replace many others, but it has its weak points, the fragility of the pipette plates and the necessity of readings being made at once before blood coagulation, which sometimes means rapid work. The Talquist scale was not tested, but he thinks that the experienced eye can, perhaps, get better results with it than can be the inexperienced one with the Fleischl instrument. The various methods of gastric analysis are given. He thinks Congo red paper is an excellent indicator for free acid, not enough used. Gunzburg's test is the best for indicating nothing but free HCl. For urinary analysis, several methods are mentioned, and as for class work and the practitioner the Ludwig-Salkowski method of testing for uric acid is hardly practicable, the Folin modifications of the Hopkins method are the best. For the volumetric determination of the chlorids the Volhard and Falck method is one of the most satisfactory, and for phosphoric acid the method described by Neubauer and Vogel, that is, adding

to 50 c.c. of urine 5 c.c. of a solution of sodium acetate 100 gms. glacial acetic acid, 30 gms. in 1 liter of water. The urine is then kept at boiling point and the standard solution of uranium nitrate added till the end reaction is reached. The tests for sugar, albumin and urea are also mentioned. Fehling's method of titration of sugar seems to be the one that is perhaps the most satisfactory in training the beginner. The Esbach albuminometer and centrifuge method are not specially recommended as accurate. The Doremus tube, especially Hinds' modification, is well spoken of, and he thinks it can be employed by the nurse as well as the physician; in fact, the keeping of a urea chart, he thinks, will become part of the nurse's duty.

48. **Albuminous Expectoration.**—This general condition is discussed and cases reported. The general opinion seems to be that it is due to acute edema of the lung, and the author thinks that this agrees with the physical signs during life as well as postmortem results. Just how edema is produced is not entirely clear. It may be due to a form of coagulation in the minuter vessels, especially the veins, from sluggish circulation. Other theories, however, are advanced, but none of them seem to be exactly supported by all facts. Probably the explanation is to be sought in abnormal pathologic conditions found in fatal cases, such as cardiac insufficiency, adherent pericarditis, clots in the pulmonary vessels, etc.

60 Management of Breech Presentations. William D. Porter.
61 *Pregnancy After the Removal of Both Ovaries. J. F. Baldwin.
62 *Condition of the Bladder After Hysteropexy. G. Kolischer.

52. **Craniotomy.**—The conclusions of Voorhees' article are:

1. That craniotomy is an operation of great usefulness, but one whose field has been narrowed to cases where the child is dead, except on occasions of grave emergency and where the mother's life would be jeopardized by a cutting operation. 2. That the operation of itself should be attended with practically no mortality in the hands of a careful operator. 3. That the cutting operations, especially Cesarean section, should be done more frequently in proper cases, inasmuch as the maternal mortality has been reduced almost to nothing in the improvement of the technic of these operations, and inasmuch as almost every baby can be saved.

53. **Histology of the Villi.**—Stahl's article is a study of the growth of villi in intra- and extra-uterine pregnancy. From his study he holds that the syncytium is fetal in its origin and it is the peripheral, muciparous stroma of the chorion or the villus as modified and added to by the ameboid activities of the nuclei (Langerhans) on their surrounding environmental tissues. There is no distinct or technical cell structure in the so-called Langerhans' cell, simply a nucleus. In intra-uterine pregnancy these infant ectoblasts are the advance posts of the villus. They make a way for the advancing villus by breaking down the tissue structures of their environment, the decidua. In extra-uterine pregnancy they are more active, as the ovum itself is here a parasite. Their metastatic growth he calls syncytioma, a characteristic name descriptive of the wandering, invading characteristics of the syncytium and its nuclei.

54. **Rupture of the Cord.**—Stowe reports a case of rupture of the cord at eight months from traumatism and discusses the accident. He has tested the strength of a number of cords and finds that the comparatively small weight of 8 1/3 pounds will break a cord 45 centimeters long, while it will stretch 26.4 per cent. of its length. In labor the rupture is favored by the greater liability of a living cord breaking than a dead one. The cord whose vessels are filled with blood and whose tissues are filled with serum is shorter in length and is more liable to internal injury. It may be hindered by the loosening or separation of the placenta.

58.—See abstract in THE JOURNAL, xxxix, November 1, p. 1,133.

61. **Pregnancy After Ovariotomy.**—Baldwin reports a case of his own personal observation where after apparently thorough removal of the ovaries, pregnancy occurred. It is possible, he thinks, that a small amount of ovarian tissue might have been left on one side or the other outside of the ligation. He also reports another case in which, after removal of the ovaries, a third body between the layers of the left broad ligament, about the size of a Lima bean, was removed and presented all the characteristics of ordinary ovarian tissue. No other similar tissue could be found, and the abdomen was closed after ventrofixation, but menstruation still continued, though the patient's condition is considerably better. These cases are of interest in connection with those reported by Doran of similar occurrence.

62. **The Bladder After Hysteropexy.**—Kolischer finds that the Alexander operation produces no effects on the bladder, but abdominal hysteropexy, ventrosuspension and ventrofixation seem to have a decided influence on its circulation and function. While exact statistics are not available it seems that with normal function before the operation the urinary calls become frequent, that the resistance of the bladder against certain morbid influences is diminished so that a slight cold causes disagreeable sensations. There is usually extreme paleness of the mucosa in these cases, sometimes a swollen and soaked appearance of the epithelium, and if stretching of the muscles be the cause of the frequent desire to micturate, it is easily understood how this might be brought about by the stretching of the bladder in case of a high, fixed uterus. Vaginal hysteropexy may affect the bladder by operative lesions. Stripping of the bladder from the uterus when imperfectly done so that the bladder coats are involved, may produce stubborn, annoying catarrh, which, however, always heals in time. Dislocation of the bladder itself does not seriously affect it, and in some cases may even improve its function, especially when the bladder is lifted up over the uterus. If the uterus is stitched too low down to the vagina it pulls the wall in such a direction as to distend the urethra posteriorly, and as this is the part involved in maintaining urinary continence, it may be impaired and operative relief be required.

63 A Few Cases of Exophthalmic Goiter. Eugene Kingman.
64 *Abscess of Lung. George S. Mathews.
65 Five Cases of Intrapopliteal Bursitis. J. C. Pegram, Jr.
66 The Milk Supply of Providence. Halsey DeWolf.

64. **Lung Abscess.**—Mathews concludes that lung abscess is not a frequent disease *de novo*. It is usually a secondary affection, and probably far more common than is supposed. It is frequently difficult to locate the abscess cavity; the greatest care and accuracy of diagnosis may be required. Pulmonary tuberculosis is the most common cause; pyemia and pneumonia are the most frequent of non-tubercular causes. He condemns the promiscuous use of the exploring needle in the absence of gangrene or where there is reason to believe the two pleural surfaces are not adherent.

71 Fourth Disease or What? Frederick T. Simpson.
72 *The Cause of Sore Arms in Vaccination. Alexander McAlister.

67. **Septic Endocarditis.**—Adams reports a case, one of four recoveries under fourteen years of age that he has found reported. The condition is discussed and the various points in regard to it reviewed. Its infectious origin is demonstrated. It seems to be rarely primary, and the author thinks that the various forms of pyogenetic bacteria may exist latent in the body and be called out by conditions of least resistance, attacking the already diseased valves.

68. **Epidemic Edema.**—Thirteen cases of edema occurring in the Providence Lying-in Hospital in infants are reported by DeWolf; 9 were fatal; 4 were discharged against his advice, and

the results not known. He analyzes the symptoms in the different cases and explains the occurrence as follows: A period of severe bowel disturbance occurring in these patients renders them susceptible to the more common infections, possibly acquired from milk. This spreading into the gastrointestinal tract produces pathologic changes in the blood and blood vessel walls besides affecting to a greater or less degree the kidneys, hence the edema.

70. **Pott's Disease.**—Gibney insists on the importance of immobilization and speaks strongly in favor of the plaster-of-paris application. He says if the visit of Professor Lorenz counts for nothing more than the removal of the prejudice against the use of plaster it will be a godsend.

72. **Vaccination.**—The cause of sore arm in vaccination is held by McAlister to be due to the lack of attention given to the patient's after-treatment. He says an operating wound is kept sterile from first to last. An accidental wound is rendered antiseptic as soon as possible, but the vaccination wound is infected with specific germs and the patient dismissed. The remedy for abnormal results is in using good virus, an aseptic technic, and treatment of the case as an important one in minor surgery.

74 *The Principles Underlying the Dietetic and Physical Treatment of Acute Nephritis. Carl von Noorden.
75 Treatment of Disease of the Gland of Bartholin. E. E. Montgomery.
76 The Correction of Bow Legs. James K. Young.

73. **Neurasthenia in Children.**—Taylor calls attention to this condition, which is not rare, as shown by lack of energy and of interest in the ordinary pursuits of childhood, and is likely to be confused with the effects of bad habits, hysteria and mendacity. The physician should always keep the psychic factor in view. Eye strain is especially noted as a cause, and should be looked for. Cardiac neuroses are common in children. The heart, lungs, blood and kidneys should be attended to. The child should have plenty of air, which is one of the best tonics. All outings and exercise should be supplemented by rest and the whole daily life of the child should be looked after. Proper food of a sufficient variety, bathing, sponge baths in warm room before breakfast, sometimes rest in bed for a few days to a week, and following a strict schedule of feeding may be beneficial.

74. **Nephritis.**—Von Noorden advises in the severe cases of acute nephritis with anuria and oliguria, increasing edema and impending danger of uremia a very limited diet consisting of about half a liter of milk a day and the avoidance of fluid nourishment as much as possible; a little ice to be sucked for the thirst or very small quantities of water. The kidneys must be spared as much as possible. The surplus water in the tissues must be removed by diaphoresis. This course can not be kept up for more than four or five days, but after that time the dangerous stage of oliguria rarely persists; the patient either succumbs or improves. Where the secretion of water is reduced, but anuria does not threaten and the edema is moderate, the diet should be milk, to which a small quantity of carbonate of lime should be added, also a sufficient amount of fat in the form of cream. The additions to the food should be such as not to irritate the kidneys, and nothing that is difficult to eliminate. He gives a daily menu, consisting in milk, cream, rice, zwieback, butter and sugar, amounting to 2,900 calories, and with 66 gms. of proteids and 160 gms. of carbohydrates and 212 of fat. In acute nephritis a diet containing so many calories is hardly required. A definite limit as to the amount of water is hard to state, but if the kidneys are capable of eliminating it, we can give it abundantly, and if in spite of good diuresis, edema persists, sweating may be indicated. As the edema disappears it becomes unnecessary. In the convalescent stage of acute nephritis the diet should be more abundant, partly of milk, but not more than 2½ liters, as more would contain too much proteid. The other articles which may be added are white bread, legumes, cereals, mild fresh cheese, some fruits, particularly grapes, small quantities of egg and meat, etc. The protein in the diet should be very gradually increased and not exceed 100 g. per diem until the nephritic process is healed. The administrations of large quantities of fluid is important at this time, and he usually prescribes a bottle a day of unfermented grape juice, which is a stimulant to the bowels and also a good diuretic. If edema appears, in spite of diuresis, as it does in some cases, some dry climate is advised. He mentions Egypt as being particularly suitable.

The Laryngoscope, St. Louis.

December, 1902.

81 Pneumatic Nasal Tampon and Splint. C. A. Leenheer.

77. **The Middle Ear.**—Stein's paper is purely anatomical, giving a description of the anatomy of adjoining parts to the middle ear and their relations.

78. **Laryngeal Cancer.**—The actual position of *x*-ray therapeutics as regards laryngeal cancer at the present time, according to Delavan, is that not a single case has been apparently reported cured, but few cases have been thus treated. In one case treated by Dr. W. J. Morton for the author, apparently good results were produced on the growth, but the patient died of Bright's disease after twenty applications of the *x*-ray. He thinks that the victim of advanced laryngeal cancer should at least be allowed the benefit of this method.

80. **Carcinoma of the Epipharynx.**—Loeb reports a case of his own observation and reviews the others in the literature, giving elaborate analyses of the symptoms. He concludes that although carcinoma of the epipharynx must be accounted as one of the rarest of affections, its symptoms declare themselves with such positiveness that a diagnosis may be made at an early stage. The early symptoms are pain, deafness, tinnitus, nasal obstruction, fetid and bloody discharge on the affected side, unilateral paralysis of the palate and some of the muscles supplied by the facial. Later symptoms depend on extension to and through the basis cranii, most commonly in the region of the foramen lacorum medium, where it comes into relation with the Gasserian ganglion. It may, however, grow more anteriorly or extend backward and involve various cranial nerves; in fact, any part of the floor of the middle fossa may be destroyed and entrance into the cranial cavity effected. With our present surgical methods there is no chance of cure, absolute or relative, and the only glimmer of hope is in the advance made in such methods as the *x*-ray treatment of dermal cancers.

83 *The Colon Douche—Its Use and Abuse. Thomas Hunt Stucky.
84 Proprietary Medicines. C. Skinner.
85 The Proper Methods in X-Ray Therapy. C. M. Mutz.
85½ Treatment of Typhoid Fever. L. F. Hammond.

82. **Mastoid Operations.**—Pfingst summarizes the indications as follows: The Schwartze operation is indicated in all cases of mastoid osteitis following otorrhea if the inflammation under treatment does not tend to resolve, and in primary mastoid inflammation when free incision of the swollen meatus fails to relieve, also in cases of purulent otitis where symptoms arise indicating brain involvement, and in protracted otitis with a profuse discharge and slight elevation of temperature, the symptoms being persistent for four or five weeks or more. Lastly, in cases of obstinate neuralgia referable to the mastoid with or without persistent otorrhea, as such are often relieved by opening the antrum and ventilating the attic. The Stacke-Schwartze operation is indicated in chronic cases of otitis media not relieved by ossiculectomy or by the removal of recurrent granulation tissue or by frequent irrigation, in which the patient complains of intermittent pains over the mastoid, even though there be no other symptoms of mastoiditis, and in protracted cases of chronic otorrhea in which symptoms indicating intracranial complications arise. In chronic cases of purulent otitis media accompanied by cholesteotomatous formation, and in all cases of extensive caries, with or without fistulous openings in the mastoid or the posterior-

superior osseous canal. He discusses the symptoms and reports cases. He would not advise operation in cases like the one reported except where the patient has frequent headaches, constant dizziness and tenderness over the bone.

83. **Colon Douche.**—The influence of this measure is far-reaching and powerful and may be damaging. Its use is many times uncalled for and in a physiologic condition can produce great harm. The important fact is not quantity, but temperature. To produce appreciable effects the age and position of the patient must be considered aside from local conditions. Considerable care must be observed in the selection of cases, and a consideration of the indications and contra-indications that may arise. Stucky notices these in detail, more especially as regards the opinions of authorities in regard to them.

87 *My Experience with Formalin in Surgery. John L. Jelks.

86.—See abstract in THE JOURNAL, xxxix, p. 1065.

87. **Formalin.**—Jelks speaks very highly of the use of formalin in various conditions. He does not think it more irritating than other agents that are employed. He finds it of special value in suppurations, ulcers, gonorrhea and infected wounds, in postpartum infections and certain skin diseases, such as tinea, etc. He thinks that stronger solution should not be used in clean open wounds or in skin granulations. Its use on the skin at the point of proposed incision is good practice and insures sterilization. In rectal surgery there is no other antiseptic so reliable. He has not had with it nearly so large a percentage of fistulæ from perirectal abscess as the statistics of authorities give and believes if the case is operated on and dressed each day after formalin irrigation fistulæ will hardly occur. In chronic dysentery he uses hot formalin solution to cleanse the mucous surfaces, with good results.

13 Case of Volvulus of the Cecum. F. R. B. Bisshopp and Alfred Fripp.

1. **The Future of Electrotherapeutics.**—Owen thinks electrotherapeutics has suffered from the apathy of the profession and has too much fallen into the hands of quacks. Its standing is not what it should be, either with the public or the profession. He draws a picture of the average practitioner looking up his old magneto-electric machine as the usual idea of applying electricity, and he recommends a large central electric institution in London to which cases could be sent by physicians to be scientifically treated, having every appliance and being the headquarters of the Electrotherapeutic Society.

2. **Simulation of Intestinal Obstruction.**—Bowlby notices at first the symptoms of true intestinal obstruction, pain, vomiting, obstruction of the passage of wind or feces, and then calls attention to the conditions that may simulate this accident, reporting cases of obstruction due to perityphlitic abscess without pain or fever, interfering with peristalsis, also cases of renal colic, gallstone impaction and acute pancreatitis, embolism of superior mesenteric artery, which acted by damaging the bowel by cutting off its nutrition, functional constipation and of enteritis. In conclusion he gives certain indications for exploratory operation, which he thinks can be followed in case it is decided to open the abdomen in order to seek for the supposed mechanical obstruction. These are the rules he has made for his own guidance and he has found it of great assistance to have a definite plan on which to proceed. He is not inclined to favor too frequent or recent exploratory operations and is conservative, but insists on careful consideration of all symptoms in an attempt to derive as nearly as possible the diagnosis before deciding.

1. Open in the middle line below the umbilicus, because most of the causes of obstruction will be found in the lower half of the abdomen.

2. Without allowing any intestine to escape, examine first, with two or more fingers, or even the whole hand, the right iliac region, and pass from there towards the umbilicus to feel whether there are any adhesions there. It is in this right lower half of the abdomen that most of the causes of obstruction are to be found, for here are: 1, the appendix; 2, intestinal diverticula, perhaps attached to the umbilicus or to the neighboring mesentery; 3, the commonest site for volvulus, that is, the cecum; 4, the usual site for the lodgment of an impacted gallstone, that is, the lower part of the ileum; 5, a common place for adhesions due to caseous mesenteric glands; 6, the sites of inguinal, femoral, and obturator hernia. Further, if the obstruction be in the small intestine, it is in the right iliac fossa that undistended intestine will be found, and if this can be secured and traced upward it is the surest guide to the seat of obstruction.

3. Examine next the left iliac region and the pelvic region, the latter, especially if the patient be a woman, for there, as additional causes of adhesions, may be inflamed ovaries or tubes or some uterine trouble with neighboring inflammation.

4. If no cause can be discovered then either open a coil of distended intestine and suture it to the skin, if the patient be too ill to bear more; or else decide to take the distended bowel out of the abdomen altogether, and if necessary open it, empty it and suture it. It is only by so doing that you will be able to return it once you have decided to let it escape, and it is often only by so doing that you will find a deeply-seated obstruction.

3. **Septic Synovitis.**—The forms noticed by Wallis are gonorrheal, influenzal, osteomyelitic, streptococcic and pyemic. The symptoms differ from the ordinary rheumatic fever in the absence of swelling and a dried harsh condition of the skin. The cutaneous and the distressed mental conditions have been well described by Rolleston, who considers the disorder of much more common occurrence than is generally suspected. The attacks usually clear up with rest and simple measures; operative interference is seldom needed, and it is not always possible to tell just what special micro-organisms are responsible.

4. **Paraffin Prothesis.**—Paget gives the results of his own experience with Gersuny's method and illustrates it with figures. He thinks it is advisable to use paraffin which has a melting point above fever heat, as embolism has followed the injection of mercurial oils and if easily softened in cases of fever there might possibly be complications. He prefers to use the paraffin melting at 110 to 115, the best being at about 110 or 111, not below it. The softer paraffins are very slowly replaced by fibrous tissue; the hard ones become encapsulated. He has never been able to get perfect results, but often very satisfactory ones.

6. **Appendicitis.**—Barling thinks he sees in the hospital experience of late years an actual increase in the incidence of appendicitis. It is not easy to give the reason why. He calls attention to a certain family predisposition to the disorder and gives an account of his own cases. He is not an advocate of indiscriminate operation, but believes in judicial selection of cases for operating. If the patient can be carried safely through his attack it should be done and operation done in the interval. The symptoms are reviewed. He does not find a constant pain at McBurney's point; this could not be expected, considering the variations of the position of the appendix. Of all the signs that might guide us as to the seat of the condition the pulse is the most valuable and reliable. Its rapidity should be indexed rather than its quality. It is not the hard, wiry pulse of peritonitis, notwithstanding peritonitis is the essential feature of the disease. It is, on the contrary, soft and yielding. It is to its rate, however, that he specially calls attention. When the onset pain is distracting the patient the pulse-beat may be 120 or 130 in the minute, but with a less intense seizure 20 or 30 beats slower is more to be expected. With diminution of the pain the pulse rate falls. If it comes to nearly normal probably other symptoms will also improve. If it should remain high, however, for more than twelve hours, the case should be looked on as a grave one unless there is some special explanation. A steady quickening of the pulse is also significant. Unfortunately the quick pulse is not always present. After the early days of the attack have passed the pulse rate will probably be of little assistance, but will be nearly normal and other symptoms, palpation, the thermometer, etc., may have to be utilized and depended on. The temperature is not a certain guide, but not to be despised. The value of the leucocyte count is considerable, but it is not infallible. He would say as regards operation we should always be guided by the severity of the symptoms present and ignore the absence of symptoms usually present or of very slight intensity if they are present. If the patient does not vomit and his temperature is approximately normal, while the pulse is 120 and the abdomen nearly rigid, lay stress on these last two points and pay little heed to the others. Or, again, if the pulse is but moderately quick and the temperature is not in correspondence and yet the patient continues to vomit despite the prohibition of mouth feeding, too great emphasis can hardly be placed on the last symptoms. If the temperature is falling and the pulse quickening, whatever the state of the other symptoms the pulse is the index to the conditions in the abdomen. He describes the operation and gives an analysis of his own cases. He emphasizes the avoidance of the repeated and persistent use of opium, which is a dangerous practice, as it misleads the patient, though the drug may be necessary to quiet pain at the onset.

14, 15, 16.—See editorial, THE JOURNAL, January 24, p. 250.

17. **Anesthesia.**—Bad subjects for anesthesia, according to Hewitt, are most generally robust, healthy, muscular individuals; the spare, sallow women are more generally the ideal patients for anesthesia. The bad subjects he considers under six heads: 1. Patients whose general health is good—possibly exceedingly good—who have some physical peculiarity rendering them more or less liable to intercurrent embarrassment or arrest of breathing. 2. Patients whose respiratory tract is in some way encroached on or whose respiration is in some way hampered by pathologic or other conditions. 3. Patients suffering from certain grave visceral or constitutional affections 4. The highly nervous or excitable patients; those suffering from various nervous affections, and those given to the excessive use of morphin, alcohol or other drugs. 5. Patients having the characteristics of two or more of the foregoing classes. 6. Patients who prove to be difficult or bad subjects without any discoverable cause. He thinks it preferable to have mouth breathing rather than nasal breathing in an anesthesia, and he has been in the habit of using a small mouth prop between the teeth soon after there is loss of consciousness.

18. **Tuberculosis.**—Beever notices the public fear of tuberculosis which has largely been aroused through medical utterances, and thinks that the disorder should be considered rather subinfectious than infectious. Direct infection is certainly rare in medical experience. While not finding evidence of infection like that of other infectious diseases, he admits that the conditions would not detect so small a percentage as 2.5 or even 5, but believes that he is justified in saying that there is not the accidental rise or fall that would indicate chance infection as in other infectious diseases to the extent of 10 per cent. It has been suggested that the latency of tubercle affords a solution of the problem. While evidence is lacking, there is a kind of latency as we find in old cicatrices and foci, and these are much more frequent in the old than in the young. The frequency of the incidence of phthisis is greatest in the young, and latency, if it took the line of origin of other infectious diseases, would show the same rise and fall and therefore this theory affords no solution. The only kind of an explanation, to his mind, in an inference which is not infrequently uttered, "We, all of us, repeatedly are exposed to infection." On the other hand, the evidences of immunity are more positive, and he notices the decrease of consumption of late years in spite of overcrowding and the increase of population, etc., which would increase the risks of infection. It is better nutrition, avoidance of infectious fever, better sanitation and ventilation that are probably the cause of the improvement. He hopes the medical profession will not encourage the public to avoid their tubercular fellow creatures. Such a course will not, in his opinion, diminish the amount of tuberculosis. It will swell the ranks of the unemployed; it will depress the phthisical wage-earner's spirit; it will empty his pockets and ultimately, by want and distress, reduce his family to that condition of low vitality which the tubercle bacillus requires for a successful invasion. To say that it does not require isolation and is infectious only under exceptional conditions, insist that healthy people may enjoy extraordinary immunity, that fresh air and open windows are the great armor against its attacks, and that the instruction of the young in the general principles of hygiene will prove more valuable eventually than the isolation measures proposed.

19. **Intermittent Fever.**—Ross suggests the use of a large drop of blood on a glass slide, slightly spread out and dried, then treated with aqueous eosin solution, which is allowed to remain for a quarter of an hour. It is then washed off by a very gentle stream of water, as the film is not yet fixed to the glass. After the eosin solution has been washed off the weak solution of methylene blue employed for the Romanowsky stain is allowed to run over the film and remain there for a few seconds, special care being taken not to stain too dark a color; then wash the blue off very gently and the preparation is complete. The stained film can now be dried and mounted or examined directly. It differs from those in ordinary use in containing no hemoglobin and will consist only of the transparent stromata of the corpuscles, the leucocytes, blood plates, and parasites. Twenty times the amount of blood used in the ordinary preparation will be found disposed over the area covered by the cover glass, and in this way it will have many times the diagnostic value of the ordinary preparation. If the Romanowsky stains are efficient the smallest parasites will be found scattered over the field as small blue rings with a deep crimson dot within or on the ring, this being the nucleus. If the preparation has not been overstained the pigment of the pigmented parasites will also be visible.

20. **Vaccination Rashes.**—Pernet describes the different forms of vaccination rashes, such as extravesical, urticarial or erythematous. Gangrenous vaccinia is a very unusual condition. Morbilliform and scarlatiniform rashes also sometimes occur, but are not troublesome. Purpura is an extremely unusual condition. Of the diseases which may be inoculated he mentions syphilis, which is rare and impossible with good bovine virus, leprosy, which he doubts, sepsis, tetanus, the excitation of diseases in predisposed individuals, accidental vaccination, horse-pox and effects of intercurrent disease on vaccination and vice versa. It has been noticed that vaccination benefits whooping cough and that influenza, pneumonia and leprosy have been improved. The symptoms of phthisis have also been modified.

22. **Diphtheria Bacillus.**—The new stain proposed by Peck is the use of Loeffler's methylene blue and Neisser's brown as a counterstain. The film is spread in the usual way, fixed in the flame, stained with Loeffler's methylene blue from three to four seconds, washed quickly, then counterstained with Vesuvian 0.2 per cent. aqueous solution for 30 seconds, again washed quickly, dried and mounted in Canada balsam. The film may be dried on the slide and stained without the use of a coverslip. This stain gives a better result in all instances in which Neisser's acetic acid stain has been used, and it has this great advantage, that it is reliable for staining the Klebs-Loeffler bacillus from a culture on blood serum several days old. He suggests as a name for it the Loeffler-Neisser method.

23. **Scarlet Fever.**—Sutherland questions the possibility of conveyance of scarlet fever by individuals passing from the sick to the well. He has been looking for such a case for several years, but without success. He has had in special investigation, which he here reports, 82 different subjects concerned; in 34 households a very well-intentioned attempt at isolation was begun and maintained for periods ranging between 21 and 43 days, but in each case was ultimately a failure, and the well children came in contact with the patient, with the result of spreading the disease. In 48 cases the sick children were isolated absolutely from the other children in the family, though the different mothers had to pass constantly from one to the other doing the housework as well as attending the sick. In none of these cases was there any extension of the disease from the sick to the well.

30 Notes of a Case of Scarlet Fever in Ranchi, Chota Nagpur. R. H. Maddox.
31 A Summary of Ehrlich's Theory of Immunity. E. D. W. Grieg.

28. **Kala-Azar.**—Bentley argues against the possible identity of this disease and malaria, pointing out the differences; the extraordinary character of the temperature curve, and the remarkable resistance exhibited by this fever to treatment by

quinin; the fact that the indigenous and long acclimatized population and not the newcomers are most subject and that malarial parasites are rarely found and such as are found are much more frequent in other localities where kala-azar has not existed. The communicability and epidemicity of kala-azar differ essentially from that usually seen in malarial disease. The fever is not the true remittent, but more like the irregular continued. It has a striking difference in this respect from the ordinary malarial.

38. **Ankylostoma.**—Sandwith offers new proof that ankylostoma can enter the body through the skin, experiments on animals (puppies) having shown this; the parasites having been found in the intestines in almost the same length of time as where it was introduced by the mouth. A man who offered himself for experiment also had applications to his forearm and ankylostomum eggs were discovered in his feces on the seventy-first day. Careful examinations were made beforehand before the introduction of the germ in each case, to be sure that there were none pre-existing.

45. **Absorption of Tetanus Toxin.**—Marie states that tetanus toxin is absorbed by the peripheral nerves, owing to a special affinity for the substance of the cylinder axis. It is attracted to the nerves with great rapidity, but the fixation is not stable. The toxin moves slowly along the nerves toward the center, and at last reaches the ganglion cell, like the absorption of nourishing juices by the roots of a plant. The motor neuron first becomes saturated with the toxin, evidenced in the localized contraction, the local tetanus. Wherever the toxin is injected it is principally attracted by the nerves of the part.

51. **Mercurial Treatment and Typhoid Fever.**—Pellot mentions that he has witnessed several instances of typhoid fever occurring in persons who were undergoing an intensive course of mercurial treatment. The saturation of the system with the mercury did not seem to have the least mitigating effect on the course of the typhoid.

52. **Ethyl Iodid in Whooping Cough.**—Amat had his pertussis patients inhale ethyl iodid and found that they were much relieved thereby. The beneficial effect seems to be similar to that derived in asthma.

53. **Treatment of Hyposthenic Dyspepsia.**—Robin allows meat, eggs and fish, but forbids farinaceous foods and bread. Green vegetables contain potash and are therefore favorable. A small dose of sodium bicarbonate a half-hour before meals is useful. After meals he orders eight drops of a mixture of 6 gm. of tincture of ignatia; 1 gm. of tincture of ipecac, and 5 gm. of tincture of illicium, taken in a little Vichy water. For lactic fermentation he prescribes two tablespoonfuls a day of a mixture of .1 to .2 gm. ammonium fluorid in 300 gm. water, taken in the middle of the meal. Mechanical antisepsis can be obtained by lavage, emetics and purgatives. He remarks that lavage of the stomach is now abandoned by those who most advocated it at one time. The indications for it are exceptional, but emetics are very valuable accessory means of realizing mechanical antisepsis. The best for the purpose is ipecac, 1.5 gm. in three doses at intervals of fifteen minutes, in a half-glass of tepid water. At the first sensation of nausea and after each effort at vomiting, another glass of tepid water should be taken so that the stomach will not be empty when it contracts. Coprostasis is very frequent in such persons although they are rarely conscious of it. Robin prefers as a laxative one or two pills at bedtime, with the formula: Barbadoes aloes, .06 gm.; extract of licorice, .06 gm.; gamboge, .03 gm.; extract of belladonna, and of hyoscyamus, āā .005 gm. The dyspnea will vanish as the distension of the stomach subsides, and with it generally the tinnitus, if not organic. If the latter persists, 1 gm. of potassium bromid once or twice a day will generally banish it; or ten drops of tincture of cimicifuga racemosa, an hour before meals, two or three times a day.

57. **Treatment of Tabes with Mercurial Injections.**—Leredde urges that mercurial injections should be made more of a routine measure and that tabes should be treated from the standpoint of 1903 and not from that of even ten years ago. The salt used is immaterial, the main point is the quantity of mercury. Injections are the only means by which we can know that we are actually introducing mercury into the system. Its action is proportional to the intensity of treatment. Fournier declares that tabes has never developed in a syphilitic treated by him for specific ocular affections, showing that adequate mercurialization at the proper moment will arrest the tendency to tabes, as the number is too large to be ascribed to mere chance. Leredde describes as an example a case showing the great benefit derived from .025 gm. of mercury injected every day for two months, in the form of the benzoate, in incipient tabes.

60. **Treatment of Renal Lithiasis.**—If piperazin be given in the dose of .15 to .3 gm. a day for three or four days, by the end of this time there will be a discharge of uric acid in the urine. Recommencing the piperazin again after five or six days, the discharge of uric acid will be noted again. These discharges are not noted under the continuous administration of the drug. Robin, therefore, prefers this method of dosing, using the solution of 3 g. piperazin in 300 gm. distilled water. One tablespoonful represents .15 gm. of the salt. One should be taken after lunch and one after dinner for the first three days of the week. The three following days he substitutes .25 g. carbonate of lithin in a little water before each meal. This treatment should be kept up week after week for months. He supplements it with weak doses of strychnin in the formula of tincture of ignatia and of illicium, āā 6 gm., six drops after meals during the two periods of treatment outlined above. He advises his patients to drink copiously, even at meals.

70. Muscular Response to the Magnet.—Féré recalls that in normal conditions the tracings of the ergograph recording the work of a muscle in action, show a gradual decline in the energy as the muscle becomes fatigued. In experiments on 27 subjects, applying a magnet 1 cm. from the forearm, showed that the muscular action was restored to its first extreme of force. As the findings coincided so constantly in all the tests, they establish that this muscular response to the magnet is an actual physical, not a mere psychologic phenomenon.

71. Study of Inconstant Albuminuria.—Daremberg's experience shows that well-tolerated albuminuria is at the minimum or completely absent in the morning. In cases of permanent albuminuria the maximum is observed between noon and 5 p. m. These are the ones influenced by diet, the others not at all. The former require alkaline treatment, the others arsenic. Massage is contraindicated in both. The range between maximal and minimal elimination of uric acid and the total acidity is much wider than in normal persons. In the latter the hourly curves of the elimination of uric acid and of the total acidity harmonize. This is not the case in subjects with morning disappearance of the albuminuria. Persons with inconstant albuminuria may even increase in weight while it continues a progressive course.

73. Hematology with Cancer of the Stomach.—Mouisset urges the importance of the decrease in the number of reds as a valuable point for differentiation of cancer of the stomach from cirrhosis of the liver, ulcer or catarrh of the stomach and especially pernicious anemia. This sign is not invariably present in the incipient stages, but is valuable when it does occur. Leucocytosis is a tardy phenomenon, seldom appearing until the period of cachexia unless induced by some inflammatory process.

75. Humoral Dyscrasia.—Valentino regards hydrorrhea, whether conjunctival, nasal or uterine, as an evidence of a humoral dyscrasia. All reveal an underlying dyscrasic affection and possess the same pathogenic and clinical qualities and importance as the edemas. Hydrorrhea may aid in the early diagnosis of a renal affection.

82. Typhoid Form of Malaria.—Billet has observed forty cases in which the malaria simulated typhoid in every particular. Diagnosis is only possible in such cases by repeated study of the temperature chart hour by hour, which will reveal some slight tendency to a periodicity in the remissions and exacerbations, although possibly extremely slight. Examination of the blood is decisive, and above all the discovery of a mononuclear hyperleucocytosis with predominance of the large mononuclear cells loaded with melanic pigment. This is the only pyrexia known with this leucocyte formula. Quinin confirms the diagnosis as it restores the characteristic intermittency and thus differentiates malaria.

84. Suprarenal Extract Injections in Addison's Disease.—Early in 1902 Hirtz treated two patients with Addison's disease by injections of extract of the suprarenal capsule. Both were clinically cured in a short time, and in one the signs of a tuberculous lesion in the lung has also disappeared. He also mentions that a number of tuberculous patients whom he has been treating with the same remedy have also improved in a most surprising manner. He is now applying it on an extensive scale and publishes the present communication merely to assert priority.

86. Injury of Eye from Contact with Podophyllin.—Rocca-Serra has witnessed a number of cases of an eye affection in operatives which was finally traced to the manipulation of podophyllin. The dust from it affects the eyes much in the same way as it acts on the intestines when taken internally, inducing a kind of neuroparalytic keratitis in time or an iritis which runs a rapid course, and subsides in a week after removal of the cause.

90. Value of Iodipin in Syphilis.—Melgarejo writes from South America that he has found that iodipin fills a long felt want for syphilitics who have an idiosyncrasy to the iodids. It is equally effective and never induces iodin poisoning, even in enormous doses.

95. Treatment of Hematoma with External Applications of Oil.—By applying oil to a bump the pain is soothed, the bump rapidly reduced and there is no appearance of a bruise. This has been the invariable experience of Camescasse with all contusions of the soft parts, with localized or diffuse ecchymosis, simply anointed with any table oil. It is not necessary to rub the oil into the skin. In one case a severe sprain improved so rapidly under application of equal parts of oil and methyl salicylate that the patient was able to resume work almost at once. In another case the prompt application of the oil caused the resorption of the extravasated blood so rapidly that the proposed damage suit had to be abandoned for lack of traces of the injury.

96. Treatment of Appendicitis.—Robin regards appendicitis as merely a complication of a gastrointestinal derangement. The first stage is gastric hypersthenia with hyperchlorhydria and secondary acid fermentations, generally on arthritic soil. This is followed by stagnation in the cecum of abnormal, acid matters, irritating from the vicious gastric preparation. This induces a catarrhal reaction on the part of the cecum and appendix. The anatomic conditions of the appendix make the catarrhal reaction ominous as the calcareous salts in the fecal matters infiltrate into the inflamed mucous and submucous coats, and infection of this recess follows. At this sixth stage of the process surgical intervention is the only treatment, but in the four first stages medical treatment will effect a cure. Signs of gastric hypersthenia and cecal coprostasis were prominent in every case of appendicitis in Robin's experience. He also has noted 82 cases of appendicitis occurring in 1585 cases of gastric hypersthenia. Castor oil or calomel are needed in the first stages; opium should be absolutely rejected. Attempts to disinfect the intestine are useless if not dangerous. He proclaims that every person with gastric hypersthenia is a candidate for appendicitis, and his cecum

should be kept under constant surveillance. Opium, as usually administered, in incipient appendicitis, merely aggravates the attack. By following the treatment outlined he has cured 244 out of 250 patients, and only 6 required surgical intervention.

101 Weitere Beiträge zum Situs transversus, etc. P. Geipel. (Commenced in No. 1.)

98. **Sudden Death in Children.**—Krautwig points out that spasm of the larynx is usually one manifestation of tetany, and both develop best in the same soil on which rachitis flourishes. The evidence to date seems to indicate that the thymus gland has some causal relation with bone growth, and, hence, with rachitis. He does not accept the mechanical connection between sudden death and the thymus which some have been proclaiming lately. He ascribes the death to the nervous disturbances induced by the rachitis, laryngospasm, convulsions, with or without bronchitic processes. He appeals to the profession to have a careful search made for stigmata of rachitis in all cases of sudden death in children. A better knowledge of the essence of rachitis may elucidate many questions in regard to sudden death in the young.

106. **Treatment of Prolapsed Gravid Uterus.**—Seitz describes a case personally observed and reviews 91 that he has collected. He finds that the results were surprisingly good so far as the mother was concerned. The fetus died in 6 cases and was not viable in 26. Lacerations occurred in only 6. In the 22 cases that have occurred since 1892, only 2 had a febrile puerperium, one died from rupture and one had a febrile delivery. The prolapse must be reduced as the first step, as the cervix dilates better in its normal position. The only exception is when the prolapse is very slight. If reduction is painful the prolapse can be swabbed with cocain or general narcosis be used. Morphin may be necessary to prevent bearing down on the part of the woman. Reduction is usually accomplished without much trouble and further prolapse can be mechanically prevented. If the cervix is too indurated to dilate, Von Winckler makes three or four very deep incisions. During extraction an assistant must hold back the uterus from below or from above through the abdomen.

111. **Primary Carcinoma of the Tube.**—Zangemeister reviews 48 and adds 3 cases he has personally observed. In 11 patients both tubes were involved. The maximum frequency was at the age of 44 to 47.

112. **Operative Treatment of Diffuse Peritonitis.**—Beck reports the particulars of 100 cases on which he has operated. Appendicitis was the cause in 66. Out of the total of 54 who recovered the stomach had been perforated in 3, the duodenum in 1, the gall-bladder in 1, the intestine torn in 2 and the bladder in 1. The perforation had been in the appendix in the others. He found the bacterium coli in 81 cases, the typhoid bacillus in 2, streptococci in 10, staphylococci in 6 and the pneumococcus in 1. In 58 the Douglas pouch could be palpated through the rectum as a painful, hard protuberance. After incision and evacuation of the peritoneal effusion by changing the position of the body, he seeks for the primary focus and then carefully dries the peritoneal cavity. He then inserts a drain under the liver and strips of gauze in the Douglas, hypogastrium, lumbar region, above and below the omentum, raises the foot of the bed, and changes the dressings in twenty-four hours. Nothing is given by the mouth, but the patient is fed by the rectum three times a day. Twice a day a "thirst injection" of salt solution is given, with digitalis and strophanthus as indicated. Also lavage of the stomach, atropin or morphin if necessary. He makes copious use of saline infusion, intravenous in the severer cases, and also gives a rectal injection at night of 100 to 250 gm. of oil, to be retained. The chief danger is from the ptomains generated in the stagnating and decaying fecal masses, which are liable to act like the most powerful heart poisons, and the septic matters of the peritoneal suppuration.

127. **Radical Operation for Spina Bifida.**—Schmidt isolates the sac from the surrounding tissues by cautious blunt dissection, then releases its contents by puncture, and reduces the sac *in toto* without opening it. The sac thus plugs the opening in the bone, and what can still be seen of the cyst is then sutured together in several tiers and the skin sutured above it. He has thus treated three patients with complete success, and no recurrence during the more than a year since, as can be seen from the photographs appended.

131. **Movable Kidney and Gallstones.**—Marwedel emphasizes the dangers likely to accrue from a movable kidney on the right side. It is liable to induce all the symptoms of a gallstone affection, typical colics, stagnation of bile in gall bladder,

etc., and icterus, while in reality the biliary passages may be intact. Compression by the displaced kidney may even lead to a secondary formation of gallstones. In case the wandering kidney is associated with gallstones or another affection which may require a laparotomy, it is advisable to anchor the kidney through the same opening. He suggests for the purpose "transfixation," and describes four cases which he treated in this manner. He pushed the kidney as far into its normal place as possible, and then fastened it with two simple mattress sutures, which from the inside passed outward through the peritoneum, margin of the kidney, musculature and skin, where they were tied over a roll of gauze in the lumbar region just below the twelfth rib. He passed one suture through the lower pole of the kidney and the other through the outer convex margin, using a stout silkworm, left for three weeks, with a straight needle on each end of the thread. He remarks that the method differs from Reed's in several points, and is recommended only for cases requiring a laparotomy for other reasons. The results have been entirely satisfactory.

135. **Treatment of Muscle Hernias.**—Steudel observes that a muscle hernia developing suddenly offers a better prognosis than one of slow occurrence. Hernias of the tibialis anticus seem to heal more readily than those of the adductors. When the hernia is small, conservative treatment is indicated, if seen early. Application of a fenestrated plaster cast, ether spray and compression are useful. But removal of the protruding portion of the muscle and suture of fascia with catgut under local anesthesia are justified even when the disturbances are not serious. A fenestrated plaster cast affords the best prospects for healing even after operative intervention. He has had 3 such cases and has collected 24 in the literature, all operated on; 13 were cured and 6 improved, but no benefit was derived in 5.

147. **Metabolism in Chronic Tuberculosis.**—The results of Mitelescu's research are given in tabulated form. They seem chiefly to emphasize the double duty which the cells have to perform in tuberculosis, besides their natural, specific functions, the production of those secretions which serve as a means of defense against the invading toxi-infection.

148. **Interruption of Pregnancy in Tuberculous Workingwomen.**—Hamburger asserts that 75 per cent. of the working women of Germany live on less than 900 marks, or $225, a year. It is impossible for a tuberculous woman, under these circumstances, to stand the stress of a pregnancy, and he therefore advises that it should be interrupted. The physician should always consult with a colleague in the matter and obtain the written consent of the parties beforehand.

151. **Antistreptococcus Sera.**—Piorkowski has succeeded in producing an effective serum against the disease of horses known as the *Pferdedrüse* in Germany. It is a streptococcus infection, but the cocci are strictly specific. The serum will agglutinate streptococci from an angina to a very slight extent, and streptococci of other derivations a little more, but will always agglutinate the specific *Pferdedrüse* streptococci at 100. He therefore rejects the theory of the uniformity of the streptococcus.

162. **Serum Treatment of Morphin Intoxication.**—Hirschlaff reports experimental research on 85 rabbits treated for three weeks to five months with small doses of morphin, commencing with .015 gm. and increasing to .51, or a maximum or 1.2 gm. a day. The animals thus received a total of 4.59 to 63.61 gm. of morphin and the rabbit serum acquired protecting power against otherwise fatal doses of morphin, both for rabbits and 100 mice. After thorough tests of the immunization thus attained, he used the serum for the treatment of one acute and five chronic cases of morphin intoxication. Some of the patients had been in the habit for years of receiving a subcutaneous injection every day, and all previous attempts at suspension of the drug had induced severe symptoms. After one to three injections of the serum, with abrupt suspension of the drug, no symptoms were observed. In the acute case a woman had taken 12.45 gm. of tincture of opium, and all the threatening symptoms rapidly passed away and the patient promptly recovered under the serum treatment.

170. **Alimentary Glycosuria in Liver Affections.**—Ferrannini tested 16 patients with various affections of the liver by administering 100 gm. of grape sugar or levulose dissolved in 500 gm. water, sipped in the course of two or three hours. The grape sugar test failed in 5, including syphilitics or patients with chronic malaria, and 2 with icterus from stagnation. The levulose test resulted positively in all but one. The response to the levulose was much more pronounced than to the grape sugar and hence it is better adapted for tests of sugar elimination than the latter. In several cases he was unable to detect the sugar in the urine by the ordinary tests, but found that Reale's modification brought it out without fail. This is a preliminary procedure, after which the urine will react to the Trommer or other tests, to which it would not respond before. Reale's technic was described in the *Riforma Med.* in 1900. About 8 to 15 gm. of neutral lead acetate are dissolved in a goblet containing 65 to 130 c.c. of urine. The fluid is filtered until clear, and to 50 to 100 c.c. of the filtrate are added 5 to 10 gm. of ammonia. A thick precipitate collects on the filter in a few minutes, which is removed with the spatula and

dissolved in a few c.c. of an aqueous solution of 25 per cent. of sodium and 20 per cent. of sodium tartrate, after which the fluid is ready for the ordinary tests. In 7 out of the 10 positive grape sugar tests the sugar was not detectable until after the application of this Reale technic. On the other hand, this preliminary was needed in only 4 out of the 15 positive levulose tests. Ferrannini has previously pointed out the value of the information to be derived in regard to the bile-forming function of the liver by tests of the lipolytic faculty of the bile. The bile-forming function may be apparently normal in a severe case of atrophic cirrhosis of the liver, for instance, but tests of this lipolytic faculty will demonstrate that it is seriously impaired.

172. **Intoxications from Hydrastis and Kerosene.**—A woman took 9 gm. of hydrastis in a single dose. The circulation and nervous system were principally affected, the digestive tract suffering only secondarily. In the other case, after taking two swallows of kerosene, a catarrhal affection of the alimentary canal was noted, but even after its subsidence the patient, a man, complained that everything smelt and tasted of kerosene. No trace of it could be detected by the odor in the breath or urine after the first day, and the sensation of its presence must have been an autosuggestion.

174. **Influence of Intestinal Contents on Strychnin.**—Salant announces that the large intestine contains a mysterious something which is able to alter strychnin in such a way that it escapes all our present means of detecting it. If 1 mg. be mixed with the stomach contents of a rabbit it is easily recovered with the usual tests. Also when added to the contents of the small intestine. But if 1 mg. be mixed with the contents of the cecum or colon, it vanishes and can not be recovered by any known test. The strychnin also disappeared in the same mysterious way from the colon of rabbits ingesting strychnin after elimination of both kidneys.

175. **Treatment of Gastric Ulcer with Olive Oil.**—Walko has previously reported the excellent results obtained in cases of gastric hyperacidity by administration of 100 to 300 gm. of oil a day. The fat inhibits the secretion of hydrochloric acid, regulates the bowels and neutralizes the excess of acid. He has since applied the same treatment to gastric ulcer with great benefit. The oil, besides the advantages enumerated, forms a protecting coating over the ulcer, soothing the inflammation and promoting healing. The boring pains subside almost at once after ingestion of the oil. It is also indicated after a gastric hemorrhage as it is less liable than milk to detach a thrombus. He gives the oil by the tablespoonful in cases of fresh ulcers, rinsing the mouth afterward with some agreeable mouth wash, gradually increasing the amount of the oil to 50 c.c. three times a day. In case of excessive repugnance he pours it into the stomach through a tube. He continues the oil treatment for three to six days, avoiding all other feeding *per os* until the severest symptoms of the ulcer have subsided. He has observed 2 cases in which the symptoms recurred after operation, but subsided after ingestion of oil. The patients are relieved in the course of the first week and consequently this method of treating gastric ulcer is shorter than others. He has had an experience of 7 recent cases of ulcer treated by this means, supplemented by rest in bed, and 2 who were out-patients, coming daily for the oil. The same arguments apply also to ulcus duodeni, and it is possible that some of the ulcers may have been located in the duodenum. Another advantage of the oil is that carbohydrates can be allowed with it, as the secretion of HCl is checked. He has recently been combining bismuth with the oil and thinks that it may be possible to obtain in this way the advantages of both these methods of treating ulcus ventriculi.

179. **A Neurasthenic Pulse Phenomenon.**—Braun observes that the arrhythmia in neurasthenia is so irregular that it has no type, and is characteristic only in its entirety. The cause is probably the excessive instability of the vagus center that controls the action of the heart. The arrhythmia can be abolished by the action of atropin. If a neurasthenic subject reclines for a long time without moving, his pulse will become regular, but if he then exerts himself the arrhythmia rapidly returns. After the pulse has been made regular in this way, an injection of atropin will keep it regular even during exercises which would otherwise reproduce the irregularity. As the other signs of the effect of the atropin wear off the arrhythmia recurs.

181. **Treatment of Anachlorhydria on Gland Stimulating Basis.**—Ferrannini has noticed that the gastric motor and absorbing functions are unaltered as a rule in anachlorhydria. When they finally yield, malnutrition and autointoxication soon follow, but the subjective and reflex symptoms are those that first attract the patient's attention. The affection is mild so long as the intestine is able to compensate the deficient stomach function. Treatment is ordinarily merely symptomatic; HCl and pepsin, bitters and intestinal antiseptics are the main therapeutic reliance. The results are frequently remarkable successful, but when treatment is suspended the trouble returns. He thinks that more durable results might be realized by addressing treatment to stimulation of the glands, instead of combating the secondary symptoms. Among the means at our command with which we could directly stimulate the secretory glands, he has tried pilocarpin and strychnin and the results encourage further attempts in this line. He describes three cases thus treated. In the first a daily injection of 1 cg. of pilocarpin hydrochlorate increased the flow of saliva, but no effect on the stomach secretion was apparent for nineteen days. Then the proportion of free hydrochloric acid in the stomach contents rose from zero to .365 per 1,000. Eight days after the pilocarpin was suspended the proportion was still .9125 per 1,000, but it declined again later and could not be revived with strychnin. The strychnin alone in a second case brought the HCl up to .0205 per 1,000 in four days, dose 1 mg. of the sulphate. It remained for four days at this point, although the strychnin was suspended. The patient was then lost sight of. This treatment also reduced the proportion of organic acids, increased the proteolytic power and also improved the motor function. All symptomatic treatment is superfluous, as by removing the cause, stimulating the production of HCl, the secondary effects vanish with the restoration of the normal acidity.

182. **Blood Pressure During Muscular Exertion.**—The increase in the blood pressure with muscular exertion is less in proportion as the will power is less called on. Consequently the rise diminishes with practice. In the young the blood pressure remains high, but in the aged it frequently drops, even during the exercise. The heart in the aged tires very easily and reacts less promptly to stimuli than the heart of the young. This communication from Dehio's clinic reiterates his former assertions in regard to the loss of the contractile tissue in the heart as age advances, producing in time what he calls senile myofibrosis, the cause of the phenomena referred to.

183. **Blood Pressure in Disease.**—Gross states that in examining 6 patients with Basedow's disease the blood pressure

was found high and variable. It is possible that certain products of abnormal metabolism act as a poison on the heart and vessels. He also notes the fact that iodothyrin has no pressure-raising action. In 5 subjects with chronic nephritis the blood pressure was also permanently above normal, but it showed marked fluctuations at this abnormal level. It was exceptionally high as symptoms of uremia developed, and fell as they subsided. This fact explains the benefit from venesection in such cases. Laqueur has reduced the blood pressure in uremia by wet packs, but Gross has succeeded by acting on the intestines and by sweats. A pressure-raising poison may be similarly responsible for the phenomena of uremia.

186. **Stokes' Symptom-Complex.**—Luce asserts that the Adams-Stokes syndrome may appear in conjunction with any organic or functional heart affection, and is not necessarily dependent on arteriosclerosis. He describes a case in which it had been induced by a primary sarcoma in the upper third of the septum ventriculorum, exhibiting the rare phenomenon of a bilateral cardiac stenosis. There were no metastases except in the immediate vicinity, but both vagi were in an advanced stage of partial parenchymatous degeneration, evidently the result of the organic lesion in the heart. Dissection of the heart also showed that the peripheral terminals of the vagi passed directly to the musculature of the ventricles, without ganglia, and demonstrated the dependence of the heart muscle on the vagi for its trophic condition. Bradycardia observed in cases of bilateral degeneration of the cardiac vagi, of central or peripheral origin, confirms the assumption of a myogenic automatism in the heart. This myogenic or neurogenic bradycardia may be regarded as the expression of an altered functional condition of the heart muscle. Deficient nourishment, general dyscrasias, toxic or infectious, and nervous influencing of the heart muscle may promote such a condition. The case also shows that complete destruction of the upper third of the septum ventriculorum or its substitution by a new growth, may occur without affecting the rhythm of the ventricular beat. On the other hand, it is possible for the rhythm of this beat to be influenced by the loss of influences emanating from the auricles. The bradycardia of cardiogenic or neurogenic origin is the essential element in the Adams-Stokes syndrome. The nervous symptoms may vary and are merely the expression of the indirect reaction of the central nervous system, especially of the medulla oblongata, to the disturbances in the circulation occasioned by the slowing of the rhythm of the heart beat. The monograph concludes with the statement that tumors of the heart do not present any characteristic clinical picture.

188. **Leukemia and Miliary Tuberculosis.**—Three cases of acute miliary tuberculosis superposed on leukemia are reported by Quincke as interesting examples of the modification of one disease by another. As certain other infectious diseases have a similar influence on leukemia we may assume, he remarks, that the microbes generate substances or induce the cells to generate them under their influence, which have a destructive action on the leucocytes in blood and spleen. We see here the reverse phenomenon to hyperleucocytosis and spleen enlargement—we can watch the subsidence of the hyperleucocytosis and the shrinking of the spleen, analogous to what we observe during convalescence from an acute disease, or during retrogression of a lymphoma or sarcoma under arsenic treatment or spontaneously. Lazarus has shown that in the course of ordinary leukemia there is a constant and fairly rapid destruction of the white cells, but that they are being constantly reproduced. This reproduction was checked by the miliary tuberculosis, as may also occur from administration of arsenious acid. The unmistakable influence of the miliary tuberculosis in these cases suggests that we might possibly be able to exert a favorable influence on the course of leukemia by administering tuberculin in which we have the tuberculosis toxins in a dosable and convenient form. Quincke has treated 6 patients on this principle, injecting doses gradually increased from 1 to 60 mg. Three of the 6 patients gave a typical tuberculosis reaction. The others did not react except to large doses. The treatment was continued for four weeks, and the leucocytes diminished by 25 to 50 per cent. In 2 the spleen also diminished in size and the general health improved. Arsenic was administered at the same time, and consequently the cases are no criterion of what tuberculin might accomplish alone. He would not advise it unless the patients were in fair general condition and the alterations in the organs not too far advanced. Under these circumstances we are certainly justified in giving tuberculin a trial as we are still so impotent in this disease.

193. **The Pancreas in Cirrhosis of the Liver.**—In 12 cases of cirrhosis of the liver that came to autopsy, a distinct proliferation of the interstitial tissue in the pancreas was evident in all but one; Langerhans' islands were intact in 11. The diminished tolerance of sugar, frequently observed in the course of cirrhosis of the liver, consequently must be due to alterations in the pancreas. The glycosuria accompanying cirrhosis of the liver, pancreas diabetes, arteriosclerotic diabetes, etc., are thus shown to have a common origin. All are due to some functional disturbance in the pancreas and confirm the assumption that this organ alone has charge of the sugar consumption in the organism.

198 (No. 11.) *Prevention of Plague. T. K. Tsukiyama. (In English.)

198. **Effectual Extirmination of the Plague.**—Tsukiyama is chief of the National Board of Health in Japan, and he proclaims that it is possible to exterminate the plague in infected cities and reports how it was done in four cities in his country. In one, Tainan, the plague has had a foothold for seven years. In the other towns the epidemic was arrested within a few months. In Tainan there were 11 cases to each 1,000 inhabitants in 1897, 32 in 1899, 24 in 1901, and only 1/22 per 1,000 in 1902. The main prophylaxis is the extermination of the rats. He states that 327,079 rats have been examined; 81,018 were caught in Tainan alone last year. Out of 14,975 examined, 172 were found infected with the plague. All these rats were caught with a simple contrivance which he illustrates. It consists merely in two smooth round bowls. The diameter of the larger one is about four times the length of the body of a rat, judging from the cuts. They are both inverted on the floor, and one edge of the smaller bowl is raised on a piece of cake. The larger bowl rests with one edge on the floor and the opposite edge on the rounding bottom of the small bowl, where it is raised on the cake. As the rat nibbles the cake the smaller bowl tottles and the larger bowl slides down to the floor, imprisoning the animal. To catch the rat one edge of the bowl is slightly raised, when the tail can be grasped. The article states that some Japanese prefer a well-cooked rat to a fish, but the infection of the family of a certain government official was traced to eating a rat, and the practice is now abandoned.

Books Received.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review, as dictated by their merits, or in the interests of our readers.

A SYSTEM OF PHYSIOLOGIC THERAPEUTICS. A Practical Exposition of the Methods, Other Than Drug-Giving, Useful in the Prevention of Disease and in the Treatment of the Sick. Edited by Solomon Solis Cohen, A.M., M.D., Senior Assistant Professor of Clinical Medicine in Jefferson Medical College. Volume V. Prophylaxis—Personal Hygiene—Civic Hygiene—Care of the Sick. By Joseph McFarland, M.D., Henry Leffmann, M.D., Albert Abrams, A.M., M.D., and W. Wayne Babcock, M.D. Illustrated. Cloth. Pp. 539. Price, $27.50 per set. Philadelphia: P. Blakiston's Son & Co. 1903.

THE PRACTICAL MEDICINE SERIES OF YEAR-BOOKS, Comprising Ten Volumes on the Year's Progress in Medicine and Surgery. Issued Monthly. Under the General Editorial Charge of Gustavus P. Head, M.D., Professor of Laryngology and Rhinology, Chicago Post-Graduate Medical School. Volume III. The Eye, Ear, Nose and Throat. Edited by Casey A. Wood, C.M., M.D., Albert H. Andrews, M.D., and T. Melville Hardie, A.M., M.D. December, 1902. Cloth. Price, $1.50. Chicago: The Year-Book Publishers.

CANCER AND OTHER TUMORS OF THE STOMACH. By Samuel Fenwick, M.D., F.R.C.P., Consulting Physician to the London Hospital, and W. Soltau Fenwick, M.D. Lond., M.R.C.P., Senior Physician to the London Temperance Hospital. Cloth. Pp. 362. Price, $3.00. Philadelphia: P. Blakiston's Son & Co. 1903.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Volume XX. Edited by Richard H. Harte, M.D., Recorder of the Association. Cloth. Pp. 571. Printed for the Association. Philadelphia: Wm. J. Dornan. 1902.

SEVENTH BIENNIAL REPORT OF THE BOARD OF TRUSTEES OF THE DELAWARE STATE HOSPITAL at Farnhurst, December, 1902. Paper. Pp. 91. Wilmington, Del.: Sunday Star Print. 1902.

COMPLETE LIST OF THE OFFICERS AND FELLOWS OF THE AMERICAN SURGICAL ASSOCIATION, Together with an Alphabetically Arranged Index of Vols. I-XX. Paper. Pp. 71.

New Patents.

Patents of interest to Physicians, Jan. 6 and 13:

718053. Water bag. Thomas Gregory, Akron, Ohio.
717898. Stethoscope or the like. Richard P. McCully, Brooklyn.
717612. Surgical chair. Charles H. Patrick, Chicago.
717764. Thermometer case. Theodore Sandhop and E. Diemar, New York.
718421. Hernial truss pad. Dudley Brisky, Milltown, Ala.
718339. Surgical splint. Andrew W. Graham, Bradford, Pa.
718202. Fountain syringe. James Hardman, Jr., Belleville, N. J.
718470. Respirator. Harold E. Jones, Racine, Wis.
718142. Cautery. John P. Muller, New York.
718149. Abdominal truss. Henry W. Pell, Rome, N. Y.
718384. Retinoscope. Wm. H. Reisner, Hagerstown, Md.
718170 Massage implement. Mary A. Sullivan, New York.
718400. Inhaler. Clarence W. Taylor, Sioux City, Iowa.
718408. Truss pad. Wm. C. Wetmore, Buffalo.

The Public Service.

Army Changes.

Movements of officers of the Medical Department, U. S. Army, under orders from the Adjutant General's Office, Washington, D. C., from Jan. 12 to 17, 1903:

Bloomberg, Horace D., first lieut. and asst.-surgeon, U. S. A., is granted leave of absence for one month, on being relieved from duty at the U. S. General Hospital, Fort Bayard, N. M.

Daywalt, George W., contract surgeon, U. S. A., now in Washington, D. C., will proceed to Fort Schuyler, N. Y., and report in person to the commanding officer of that post for duty and by letter to the commanding general, Department of the East, to relieve First Lieut. Theodore C. Lyster, asst.-surgeon, U. S. A., who, on being relieved, will proceed to West Point, N. Y., and report in person to the superintendent of the U. S. Military Academy for duty.

Kirkpatrick, Thomas J., captain and asst.-surgeon, U. S. A., is granted leave of absence, to take effect on his relief from duty at Ft. Barrancas, Fla.

Maxwell, Samuel A., contract surgeon, U. S. A., is relieved from duty at Fort Grant, Ariz., and will proceed to San Francisco, and report in person to the commanding general, Department of California, for transportation to the Philippine Islands, where he will report in person to the commanding general, Division of the Philippines, for assignment to duty.

Norman, Seaton, major and surgeon, U. S. V., now at San Francisco, will proceed to his home, where he is authorized to await his honorable discharge from the service of the United States, Feb. 1, 1903.

O'Neill, Joseph A., contract surgeon, U. S. A., will, on the expiration of his present leave of absence, proceed to San Francisco, and report in person to the commanding general, Department of California, for transportation to Manila, Philippine Islands, and on his arrival in Manila will report in person to the commanding general, Division of the Philippines, for assignment to duty.

Turnbull, Wilfrid, first lieut. and asst.-surgeon, U. S. A., having reported his arrival in San Francisco, will proceed to Fort Myer, Va., and report in person to the commanding officer of that post for duty.

Wood, Halsey L., contract surgeon, U. S. A., is relieved from further duty on the transport Warren and will proceed to Vancouver Barracks, Wash., and report in person to the commanding general, Department of the Columbia, for assignment to duty.

Navy Changes.

Changes in the Medical Corps of the Navy for the week ended January 17:

P. A. Surgeon H. H. Haas, ordered home via *Prairie*.

P. A. Surgeon J. E. Page, detached from the *Newark* and ordered to the *Montgomery*.

P. A. Surgeon F. L. Benton, detached from duty with recruiting party, ordered to Washington, for assignment with battalion of marines, leaving for the Philippines.

Drs. R. L. Taylor, W. P. Keene, D. E. McCord and W. H. Janney, appointed acting assistant surgeons for three years' service.

P. A. Surgeon C. A. Crawford, resignation accepted, to take effect Jan. 12, 1903.

Drs. R. B. Chapman, H. W. Judd, J. T. Miller and R. A. Campbell, appointed acting assistant surgeons for three years' service.

A. A. Surgeon D. P. McCord, ordered to Lansing, Mich., for duty with recruiting party.

A. A. Surgeon R. L. Taylor, ordered to Ogden, Utah, for duty with recruiting party.

P. A. Surgeon W. H. Bucher, detached from Naval Hospital, Norfolk, Va., and ordered to Naval Hospital, Pensacola, Fla.

Pharmacist F. T. Gordon, ordered to the Naval Dispensary, Washington, D. C., for duty.

Asst.-Surgeon R. E. Ledbetter, detached from the *Illinois* and ordered to the *Newark*.

Marine-Hospital Changes.

Official list of the changes of station and duties of commissioned and non-commissioned officers of the Public Health and Marine-Hospital Service for the seven days ended Jan. 15, 1903:

Assistant Surgeon-General J. H. White, to proceed to Brunswick, Ga., for special temporary duty.

Surgeon H. R Carter, leave of absence for three days under Paragraph 179 of the regulations, amended so that it shall be for two days only.

P. A. Surgeon G. M. Guiteras, to report to chairman of board of examiners at Washington, D. C., Jan. 15, 1903, for examination to determine his fitness for promotion to the grade of surgeon.

P. A. Surgeon J. H. Oakley, granted leave of absence for two days from January 21.

P. A. Surgeon C. H. Lavinder, granted leave of absence for one month from January 28.

A. A. Surgeon B. F. Duke, granted leave of absence for ten days from January 4.

A. A. Surgeon W. S. Walkley, granted leave of absence for five days from January 13.

BOARDS CONVENED.

Board convened at Washington, D. C., Jan. 15, 1903, for the examination of P. A. Surgeon G. M. Guiteras to determine his fitness for promotion to the grade of surgeon. Detail for the board: Assistant Surgeon-General L. L. Williams, chairman; Assistant Surgeon-General W. J. Pettus; Assistant Surgeon-General G. T. Vaughan, recorder.

Board convened at the Marine Hospital, Stapleton, N. Y., Jan. 17, 1903, for the physical examination of Engineer D. F. Bowen, R. C. S. Detail for the board: P. A. Surgeon A. C. Smith, chairman; Asst.-Surgeon A. J. McLaughlin, recorder.

Board convened at the Marine Hospital, San Francisco, Jan. 19, 1903, for the physical examination of officers of the Revenue Cutter Service. Detail for the board: P. A. Surgeon W. G. Stimpson, chairman; Asst.-Surgeon C. W. Vogel, recorder.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended Jan. 17, 1903:

SMALLPOX—UNITED STATES.

California: Sacramento, Dec. 27-Jan. 3, 1 case.
Colorado: Denver, Dec. 27-Jan. 3, 7 cases.
Connecticut: Thompson, Jan. 10, 1 case.
Florida: Pensacola, Dec. 6-Jan. 10, 49 cases.
Georgia: Atlanta. Dec. 24-Jan. 7, 14 cases, 3 deaths.
Illinois: Chicago, Jan. 3-10, 6 cases.
Indiana: Evansville, Jan. 3-10, 1 case; Indianapolis, Dec. 27-Jan. 10, 95 cases, 16 deaths.
Kentucky: Covington, Nov. 27-Jan. 10, 82 cases, 2 deaths; Newport, Jan. 3-10, 2 cases.
Louisiana: New Orleans, Jan. 3-10, 1 case.
Maine: Biddeford. Jan. 3-10, 7 cases; Boston, Jan. 2-9, 10 cases, 3 deaths: Cambridge, Jan. 3-10, 2 cases; Fall River, Jan. 3-10, 2 cases; Lowell, Jan. 3-10, 1 case.
Michigan: Detroit, Dec. 27-Jan. 10, 78 cases; Grand Rapids, Jan. 3-10, 18 cases.
Missouri: St. Louis, Dec. 28-Jan. 4, 9 cases, 1 death.
Nebraska: Omaha, Jan. 3-10, 11 cases.
New Hampshire: Jan. 3-10, Manchester, 2 cases; Nashua, 3 cases.
New Jersey: Camden, Jan. 3-10, 3 cases; Newark, Dec. 27-Jan. 10, 1 case, 1 death.
New York: Jan. 3-10. Buffalo, 2 cases; New York, 1 case.
Ohio: Cleveland, Jan. 3-10, 9 cases, 2 deaths; Dayton, Jan. 3-10, 2 cases; Toledo, Dec. 27-Jan. 10, 26 cases, 1 death.
Pennsylvania: Altoona, Jan. 3-10, 2 cases, 2 deaths; Erie, Jan. 3-10, 10 cases, 1 death; Johnstown, Dec. 27-Jan. 10, 2 cases, 1 death; McKeesport, Jan. 3-10, 1 case; Northumberland, Dec. 1-30, 14 cases; Philadelphia, Jan. 3-10, 33 cases; Pittsburg, Jan. 3-10, 22 cases, 1 death; Reading, Jan. 5-12, 1 case.
Tennessee: Memphis, Jan. 3-10, 1 case.
Utah: Salt Lake City, Dec. 27-Jan. 3, 10 cases.
Wisconsin: Milwaukee, Jan. 3-10, 5 cases.

SMALLPOX—FOREIGN.

Austria: Prague, Dec. 6-20. 25 cases.
Barbados: Dec. 5-20, 2 deaths.
Belgium: Antwerp, Dec. 6-20, 10 cases, 3 deaths; Brussels, Dec. 13-20, 1 death.
Canada: Winnipeg, Dec. 27-Jan. 3, 1 case.
France: Paris. Dec. 13-20, 1 death.
Great Britain: Cardiff, Dec. 20-27, 1 case; Dublin, Dec. 20-27, 1 case; Dundee, Dec. 13-27, 2 cases; Leeds, Dec. 20-27, 3 cases; Liverpool, Dec. 20-27, 74 cases, 1 death; London, Dec. 13-20, 5 cases; Manchester, Dec. 13-27. 7 cases; Sheffield, Dec. 13-27, 8 cases.
India: Bombay, Dec. 2-9, 7 deaths; Calcutta, Nov. 27-Dec. 6, 2 deaths.
Mexico: City of Mexico, Dec. 28-Jan. 4, 2 cases, 5 deaths.
Russia: Moscow, Dec. 6-13, 2 deaths; Odessa, Dec. 6-20, 7 cases, 2 deaths; St. Petersburg, Dec. 13-20, 24 cases, 2 deaths.

YELLOW FEVER.

Mexico: Tampico, Dec. 27-Jan. 3, 10 deaths; Tuxpam, Dec. 23-30, 1 death; Vera Cruz, Dec. 27-Jan. 3, 6 cases, 2 deaths.

CHOLERA.

India: Bombay, Dec. 2-9, 1 death; Calcutta, Nov. 27-Dec. 6, 51 deaths.
Java: Batavia, Nov. 22-29, 6 cases, 2 deaths.

PLAGUE.

India: Bombay, Dec. 2-9, 133 deaths; Calcutta, Nov. 28-Dec. 6, 25 deaths; Karachi, Nov. 30-Dec. 7, 12 cases, 11 deaths.
Mexico: Ensanada, to date, 14 cases, 13 deaths; Mazatlan, Dec. 31, officially reported.

Addresses.

HOW NOT TO BE NERVOUS.*

HUGH T. PATRICK, M.D.

Professor of Neurology, Chicago Policlinic; Clinical Professor of Nervous Diseases, Northwestern University Medical School.

CHICAGO.

Nervousness seems to be the stepchild of medical practice—somewhat disliked, half understood, certainly neglected. For the average practitioner no problem in the theory of organic disease is too profound for attempted solution, no law of life too exalted for his aspiration, no bacillus so small as to elude his pursuit, but with such a triviality as nervousness, its nature, prevention and cure, he seldom seriously occupies his mind. To acquire a working knowledge of the brain is too much bother. To ponder the plain facts of heredity, development and child-rearing is too uninteresting. To cultivate a familiarity with the various passions and emotions, to search out manners of thought and feeling, or even to discover the dominating element in the life of a patient is quite impractical. To take the time to counsel those about to marry or to instruct the mother how not to spoil her children; to caution the father about his erratic son and give detailed instruction how to make him stable; to talk seriously to the young woman who is "all nerves" and lives in her emotions; to reason clearly and forcibly with the head of a family who is preparing himself for a premature break down—these are minor matters pertaining—to whom? to what? God knows, the physician does not. And yet if you will stop for a moment, take your finger from the pulse and your hand from the scalpel, your eye from the microscope and your thoughts from the microbe, I think you will agree with me that these trivialities contribute quite as much to human suffering and disappointment as do the infections, inflammations and neoplasms in the long category of human pathology. No apology, therefore, is made for the following remarks on that pest, nervousness. My regret is that an abler mind is not here to do the subject justice.

The initiative of all therapeutics should be prophylaxis; prevention is paramount to cure. The first and most effective preventive of nervousness is a reasonably long line of first-rate forbears. Like begets like, and the nervous system bows to the law of all life—the law of heredity; the law that governed your birth and mine and laid a heavy incubus on some of us; a burden of unstable nerves and abnormal susceptibilities; a burden that endures even unto the third and fourth generations.

To be able to present a specific illustration of the force of inheritance in the genesis of functional nervous affections, I have tabulated from my office records one hundred consecutive cases which might be included under the general term "nervousness," and I find that in 70 of them a neurotic heredity has been in evidence. Although a bad heredity is the most frequent and most potent factor in the production of nervousness, knowledge of this fact is not to lead us into apathetic resignation, but rather make us face the difficulty with wise determination. The poor victim, instead of being allowed to dissipate the modicum of stamina a bitter fate has given him, is first to be shown just what his capital is, and then is to be taught just how to make the most of it.

Next to the omnipresent, inevitable laws of inheritance comes the never-ceasing formative power of environment. The impress of extraneous influences begins at birth and ceases only with the extinction of life, but childhood and youth are the plastic stages. Here, as elsewhere, the result equals the force divided by the resistance. "As the twig is bent the tree's inclined," and second only to the mystic law of birth, which decrees that the nervous system shall have this or that potentiality, is the force that guards or mars its early growth. Unfortunately, in too many instances the unstable and maybe irrational parents who gave to the child his poor nervous apparatus are the ones who guide, or misguide, his early steps into the perdition of nervous wreckage. To look on such a child with the assurance that he is growing up to be the victim of nervous unbalance, inebriety or insanity, should not be idly to feel the despair of conscious impotence, but should be coexistent with an effort to avert the disaster. Wherefore, I beg to say a few words that bear particularly on nervousness in the child and its avoidance, but with this understanding, that they apply almost equally to the adult, and that what is said later about grown people applies to children to the extent of their development.

For preventing nervousness in the child or removing that already present, nothing is so effective as the toughening of the body and mind. The frequency with which I hear from a nervous patient that "she was never strong," "he was a delicate child," "she was always sickly," etc., is truly startling. A child who is made to have hard muscles, strong lungs and a vigorous digestion; who can bear changes of temperature and endure pain is already a long way from nervousness. More important still is toughness of psychic fiber. The child who can support disappointment, who can be "crossed" without a tantrum, and who habitually obeys is building a bulwark against "nerves," and the one who is not easily frightened, has self-control and a budding courage

* Address in Medicine, delivered before the twenty-eighth annual meeting of the Mississippi Valley Medical Association, Oct. 16, 1902.

has nipped half a dozen neuroses in the bud. But to procure this toughness, be it understood, a certain exposure to bodily discomfort and mental hardship is necessary. This world is no "Happy Valley," and children brought up like Johnson's Rasselas are as little happy and as little able to cope with the realities of life as was that puerile prince. Many a father whose rugged rearing has given him a robust frame and a sturdy nervous sytsem takes infinite pains and pleasure in denying his sons the very training that made a man of him. His unwise love strangles in infancy whatever of sterling qualities he may have transmitted to them.

Two capital errors in the training of children frequently come to my notice; errors that prepare the little unfortunate for later nervousness or fairly drive him into it. They are, first, leading the child into pleasures and duties beyond his years; second, magnifying his importance in the family and society. It is quite as dangerous to give to children the pleasures of adults as to require of them the labors of the mature. That there is a physical basis for all intellectual processes seems sometimes to be forgotten. Successive groups of brain cells and fibers come into existence with the successive years, and before the birth of these tissues certain psychic functions may not naturally exist. To force mature functions from an immature organism is to violate the virginity of Nature—a crime daily committed in the home and in the school, to be expiated in the sick-room, sanitarium or asylum. In the beginning, the fault generally lies in a mixture of vanity and ignorance on the part of parents. They wish their children to excel in attainment and they like to see them indulging in all the pleasures and excitements of our complex social existence. Later, the young person whips himself on to ruin. To instance only one disaster: the annual casualties following graduation from hot-house schools and colleges easily outnumber those of the whole disastrous camp life and battles of our late Spanish war.

As regards the second error just mentioned, it has seemed to me that if deliberately planned and scrupulously executed, the bringing up of some children could not better promote what I venture to call centripetal development—development centering in self. The child is not only made to be, but is made to know that he is, the focus of all domestic doings, the hub of the family wheel. Every sensation, perception, conception and emotion is an event. The unlucky youngster develops with a distorted view of the relation of things. He sees enormously enlarged images of his tastes, his clothes, his pains, his likes, his aversions and his talents. These proportions do not fit the facts of existence and the unfortunate individual is as sure to be caught in some form of nervousness as is one to go astray in a labyrinth of grotesque mirrors.

I must note one more point on prophylaxis of the neuroses in children, a point already lightly touched, and then we shall leave the little people—much as I should like to linger. In one form or another fear enters into the makeup of nearly every sort of nervousness. It paralyzes judgment, ambition and the higher emotions. Childhood should be absolutely fearless; fearless for self and for the future. That the young should have no fear of man or God, no thought for the morrow is natural and proper. It is natural and wholesome that the child should have no regard for his organs, no knowledge of hygienic rules, no conception of the significance of pain. When the parent makes the child a party to his apprehensions, confides his prescience of ills and communicates the ominous augury of bodily symptoms, he is assiduously rearing a little hypochondriac who will live to condemn the parent who made him a burden to himself and a curse to others. Fear of the dark, of thunder and lightning, of animals, burglars, accidents, spirits, devils and death is born of parental foolishness, and is always potentially the seed of later nervousness. Quite recently a physician, who for many years has had at intervals typical and intense agoraphobia with fear of sudden death, told me with the utmost naivete that when a child he never could sleep alone. It seems never to have occurred to him that if he could not sleep alone it was because he was allowed to have such a fear, or, quite as likely, because the parents carelessly or deliberately planted fear in his infant mind.

After birth and bringing up, after the facts of heredity, childhood and youth comes adult life—the life of man and woman. But they are as children still, mutable, mobile, imperfect always, swayed by a thousand influences, slaves to countless circumstances. How shall they manage not to be nervous? By proper living; proper working and playing, eating, drinking and sleeping; above all, proper thinking and feeling.

Labor may have been a calamity to Adam and Eve. Nowadays it is no curse, but the bright particular star of health and happiness. To have a wholesome ambition and to work with enthusiasm for its fulfilment, these form the very essence of a vigorous existence. Fortunately, man is now so constituted that to work, and work with an object, is a function necessary for his completeness. To cross this dictum of Nature is to suffer—physically, mentally or morally, in many instances nervously. Many an invalid would be well today if he had a worthy purpose in life and happily labored for it. Many a hysterical woman would be stable and strong had she consistently striven with singleness of aim for a laudable object. The purposeless idler is ever a weakling in unstable equilibrium, upset by every vagrant mood.

To say that overwork is not a very frequent cause of nervousness is frankly to enter the ranks of heterodoxy, but my experience is that work, hard work, is wholesome. To work hard is to get tired; to work too hard is to get too tired; but I seldom see the familiar spectacle of nervous breakdown due to work alone. It is the unwisdom that goes with the work. It is worry, the strain of doubt, the wear of ungratified ambition, the depression of failure or the passionate play of other emotions that makes the nervous wreck.

Though man's nature demands work for his development and equipoise, it none the less needs play. Long before the birth of physiology it was known that the greatest efficiency of any living tissue was attained by alternating activity and rest. The cycle of the seasons, the night following the day, the succession of blossom, fruitage and quiescence, the universality of holidays, are so familiar as to cause no thought, but all life is attuned to this wonderful rhythm of action and repose. Even the busy heart that never ceases throbbing day or night from birth to death, so beats that every contraction is followed by a period of rest almost twice as long. That is, a healthy heart works only about one-third of the time. What is a good law for the heart is not a bad rule for the brain, but for this complex creature called man, something more than mere rest is necessary. Be-

sides relaxation we must have diversion, amusement, fun, if you please. We must play if our work is to be effective and long sustained and if we are not to be nervous.

The advisability of reasonable eating, the pernicious effects of alcohol on the nervous system and the havoc wrought by drug habits are so universally recognized as to need no mention. With respect to diet, however, I can not refrain from noting one bad habit that has seemed to me to be very frequent in nervous people and to contribute materially to their troubles. I mean the starvation habit—the obsession, born of poor doctors or officious friends, that makes the victim eschew one article of food after another until he is trying to exist on Fakem's nularine and Buncombe's cereal.

Of all nervous sedatives and tranquilizers of mankind none equals "tired Nature's sweet restorer, balmy sleep." Sancho Panza truly said "it is meat for the hungry, drink for the thirsty," and, as a matter of fact, we know that one can live without sleep just about as long as he can live without food. Children should be encouraged to sleep, young people should be made to sleep and the nervous person should be taught to sleep. The sins of parents who carelessly or designedly shorten the children's sleep hours is only equaled by the folly of grown-ups who deny themselves sleep for the sake of business or pleasure. Alarm clocks are an abomination unto the brain and an evidence of hygienic evil.

A deal of nervousness is caused or helped along by misdirected energy, misplaced worry, longing for baubles, the fighting of phantoms. To recognize the really important things in life is one of the most difficult tasks of judgment that come to the individual. Having settled on the essentials, it is perhaps equally difficult to ignore all else. This is certain; the man or woman who can early reach a wise decision in the matter and then steadily follow the tenor of this decision could not be nervous, even with the aid of ancestors and the connivance of parents. Fretting over non-essentials, striving for objects not worth the having, fright at empty forms, looking inward at little self instead of outward at the greatness of creation—these are the follies that keep us nervous. And closely allied to them is the nervousness of indecision—the demon of reconsideration. How many thousands of people have worn themselves to nervous shreds by turning over and over the same problem, reaching again and again the same conclusion. It is well worth while to acquire a habit of prompt and definite decision. To allow one's self to reopen settled questions begets a habit of doubting one's ability, or even reliability, pernicious in the extreme.

If to define for one's self the really great and valuable is important, equally so is the determination of one's own place and one's own value. Realization of the fact that the individual is merely a minute item in a limitless cosmos, at most a not very important integer in a complex society, should be the first step toward a rational adjustment of values on which must rest that serene placidity which is the antithesis of nervousness. To be plainer still, the person who is brought up, or brings himself up, to feel that he is of paramount importance; that his feelings, wishes and opinions are always entitled to prompt consideration, is on the very highway to nervousness. He is doomed to much disappointment; many rude shocks to his sensibilities breed a gnawing bitterness of spirit; he naturally gravitates into the neuropathic vice of introspection. To develop the conception that he is peculiarly constituted; that he is a wonderfully unique organization of finer mechanism than his fellow-mortals, is continuously calamitous for anyone. As a matter of fact, one man's stomachache is much like another man's colic, one woman's aversions about as strong as another woman's antipathies, A's grief as keen as B's sorrow. The perfectly normal individual carries as part of his innermost consciousness the knowledge that pain, tears and troubles come to all and that what has been borne by man for countless ages can be endured again. Such knowledge, too, must in part form the natural base of true altruism and effective ethics. That lofty ethics should constitute a goodly plate in the armor against nervousness is seldom mentioned, but practical experience has time and again taught me that sincere love of truth, justice and self-control is a mighty help in the fight against nervous instability. Of particular value are a clear appreciation and uniform practice of the exact truth. They are the best protection against nervous trouble whose essential feature is repeated exaggeration and self-deception, if not deception of others.

Sooner or later, consciously or unconsciously, every ambitious person must make a more or less deliberate estimate of his ability. Blest be he who does it early and accurately. Ambition is a wonderful force and makes for progress; emulation is an excellent stimulus, and industry is better than both, but in excess the combination has worked the nervous ruin of many. The young man of high aims who wishes to rival the success of a Lincoln, an Astor or a Virchow, and who thinks that the only necessary conditions are industry, honesty and frugality, makes an egregious error. He reckons in ignorance of two stupendous factors: physical endurance and mental capacity. These are facts as indubitable and as inevitable as death itself. It must come to every physician, it certainly comes frequently to me, to explain to the nervous student that because his colleague can keep well on five hours of sleep is no reason why he should be able to do the same; to show the irritable, sleepless business man that even if his competitor can work fifteen years without a vacation, he can not do likewise; to convince the ambitious Mrs. X. that she simply is not equal to the attainment at the same time of domestic excellence, social eminence and philanthropic distinction as is the brilliant Mrs. Y.; and to tell the disappointing truth to many that although some fortunate beings are given master minds in master bodies, this gift is not for all, and that to spur on the weary faculties is to drive to ruin. Still, if one must plainly see that his talents are far below the maximum, even far below what he had hoped and believed, why should he dissipate what he has in attempting to be what he is not and in fretting because he can not? How many of us exhaust ourselves and wear out our friends by chafing against the chains of the unalterable! Imperturbability is a prince of peace.

Of especial danger is the weakness of being ruled by the feelings—by emotion rather than by reason, by impulse rather than by judgment. In the bitterness of recognized folly and acknowledged frailty, Burns wrote for his own epitaph:

* * * * * *

Is there a man whose judgment clear,
Can others teach the course to steer,
Yet runs himself life's mad career
Wild as the wave;
Here pause—and, through the starting tear,
Survey this grave.

The poor inhabitant below,
Was quick to learn and wise to know,
And keenly felt the friendly glow,
And softer flame;
But thoughtless follies laid him low,
And stained his name!

Reader, attend,—whether thy soul
Soars fancy's flights beyond the pole,
Or darkling grubs this earthly hole,
In low pursuit;
Know prudent, cautious self-control
Is wisdom's root.

If this was written with the plaintive note of a sensitive spirit prisoner to turbulent passions, it was also written in the light of a keen perception. A principle of human development is bound up in the lines. The head is to guide the heart. Impulse and emotions are to be governed by knowledge and wisdom.

Inhibition should never sleep. Exaggeration of the instinct of fear and apprehension not only makes people nervous, but is nervousness itself. The thousand and one needless worries over the future are simply providence for the morrow gone mad. Fear of disease and death is normal, but to allow the mind to dwell on these fearsome things is to become a hypochondriac with no more stability than the leaf on the aspen. To shrink from pain is as natural as hunger and as necessary for the preservation of the race, but to be a slave to suffering is to be a nervous wreck. Pain should be a signal officer only—to inform, never to command. Even the godly emotion of parental love must not be too exuberant. How many mothers become mere bundles of nerves through needless fussing about the children, and how often a father falls into presenility from the constant strain to feather the nest superlatively well. To weep is normal, but the one who never restrains the impulse to cry ultimately becomes flabbily lachrymose, a nuisance to self and others. Every human being has, now and then, a "fit of the blues," but he who allows himself to be regularly dominated by mental depression becomes an enervated personification of gloom, a victim of the most distressing form of nervousness.

To sum it all up, if you wish never to be nervous, live with reason, have a purpose in life and work for it, play joyously, strive not for the unattainable, never regret the unalterable, be not annoyed by trifles, aim to attain neither great knowledge nor great riches, but unlimited common sense, be not self-centered, but love the good and thy neighbor as thyself.

THE SCIENTIFIC EXHIBIT AND ITS FUTURE.

CHAIRMAN'S ADDRESS, DELIVERED BEFORE THE SECTION ON PATHOLOGY AND PHYSIOLOGY, AT THE FIFTY-THIRD ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION, AT SARATOGA SPRINGS, N. Y., JUNE 10-13, 1902.

FRANK B. WYNN, M.D.
INDIANAPOLIS.

The modern medical society has wrought powerfully for the advancement of scientific medicine, stimulating investigation, discovery and authorship, adding to the knowledge of methods in diagnosis and treatment, and fostering professional cordiality. Intelligent and progressive physicians were quick to appreciate the value of the society movement and give it their enthusiastic support. Three decades have witnessed most prolific multiplication of medical societies. There are county, district, city, state, interstate, national and international organizations, representing the field of general medicine and the specialties. As with medical colleges and journals so may the tendency to society multiplication be deplored. A worthier criticism might be offered on the volume and character of matter read at society meetings. The views herein expressed are more especially applicable to the larger organizations which convene annually. It may be asserted without fear of controversy that too many papers are submitted. A few only have just claim to originality; some are attractive and vigorous in style, others are conspicuous for their tedious length and dreary compilations. Taken all in all the effect even on the most attentive listener is too often somnolent.

Present problems of society reform call for the curtailment of programs, the condensation and elimination of papers and the introduction of practical features which will entertain, instruct and make plain the latest advances in medical science. The surgical furor of the day has led occasionally to the operative clinic as a practical and interesting digression from the monotony of the usual program. But the valid objections are raised that it consumes much time and the personal advertisement it gives is apt to lead to professional criticism and discord.

Prompted by a conviction that there were other practical features less objectionable and equally interesting which might be made valuable adjuncts of society work, the committee on pathology of the Indiana State Medical Society made an appeal to the membership in 1897 for gross pathologic specimens and scientific exhibits of varied character, to be shown at the succeeding meeting. Agitation, appeals to local and professional pride and personal solicitations were resorted to, according to occasion and requirement. Most fruitful results followed the appeal. The number of exhibits reached almost 200 in 1898, and 800 in 1899, representing a wide range of material. Besides gross pathologic specimens, photographs, etc., the collection included bacteriologic demonstrations, such as the Widal test, guinea-pig and culture experiments, which presented tangible proofs of the important relationship between bacteriology and diagnosis, as well as its bearing on surgical and sanitary procedures.

The sentiment of members attending the meeting in 1899 was unanimously commendatory of this unique departure. Approval was forcibly expressed by appropriating $300 to bear the expense of taking the major part of the exhibit to the Columbus meeting of the American Medical Association the following week. Its cordial reception at that place was most gratifying to the Indiana profession. Interest in the movement was awakened in different quarters. Several state societies sought to establish a similar exhibit. Although not officially authorized to act, Dr. W. W. Keen, President of the American Medical Association, appointed a committee to take steps to inaugurate a pathologic exhibit at the Atlantic City meeting of the organization in 1900. The success of the project was gratifying alike to the executive officers of the Association and to the committee having in charge the work. It was a wholesome change to have an exhibit purely scientific and free from commercial taint. The Association signified its approval by making the feature permanent and granting a liberal appropriation for its maintenance.

The full consummation of the Pathologic Exhibit in a national and official sense was not achieved, however, until the meeting at St. Paul a year later. Profiting by the experience at Atlantic City it was hoped to secure

for St. Paul a better balanced exhibit, both in the scope and character of the material. In addition to practical exhibits, it was sought to present demonstrations of research and experimental investigation. In the main these hopes and desires were realized. The size and quality of the exhibit were in keeping with the great organization under whose auspices it was conducted. When it is remembered that the enormous labor necessary in the preparation and presentation of the exhibit was performed gratuitously by exhibitors, one can but marvel at the results attained. It afforded eloquent proof of the utter unselfishness of the true scientific spirit. A corps of over fifty pathologic workers labored faithfully at home for the success of the enterprise, and at the St. Paul meeting subordinated pleasure to the successful demonstration of the exhibit. It was made a great common school of pathology for all who attended the meeting. The laborers in the good cause have merited and won the grateful thanks and unstinted praise of the whole Association.

It is not possible at this time to speak of the present exhibit in detail. An official report will be submitted by the chairman of the committee at a later date. Brief mention should be made, however, of the admirable work accomplished by the committee. Although not so extensive as that at St. Paul, the present exhibit has enlarged along important lines inaugurated a year ago. Especially is this true of the research and physiologic exhibits in which a very creditable showing has been made.

To describe accurately the St. Paul exhibit would require a volume. One might easily have spent the entire time of the meeting in the inspection of the 2,100 specimens. The room occupied by the collection was 75x75 feet, lighted well on two sides, but unfortunately most inconvenient of access. Consequently the attendance, although large, was not what the excellence of the exhibit warranted.

Four medical societies, nine medical colleges and universities, ten hospitals and museums of national prominence contributed. There were in addition six large private collections.

Although the assembling of such a magnificent array of material was an achievement over which the committee felicitated themselves, I am free to confess that the magnitude of the collection was a hindrance to its greatest usefulness. Careful observers must have been impressed that only casual and superficial inspection of the specimens was possible. It was found entirely out of the question to secure a sufficient number of competent persons to demonstrate the specimens. Hence a large quantity of valuable material stood on the shelves unseen and impotent for educational advancement—the prime end sought.

In the further evolution of the pathologic exhibit of the American Medical Association, a wider sphere of usefulness will be opened up if the name be changed to Scientific Exhibit. This would insure greater range of scientific demonstrations, and enlist more general cooperation on the part of members. It should be made plain that the exhibit belongs to the whole Association. Further gain will be made if the exhibit be placed in entire charge of a director, who should be chosen by the board of trustees and receive a fair salary for the labor performed. In his hands should be placed funds for the encouragement of research and experimental work. Let the exhibit become the arena in which the investigator demonstrates to his co-workers the proofs of original work. Papers and reports are valuable in their way, but "seeing is believing." What in this way can be made plain to many competent witnesses will be spared the innuendos of skepticism and receive just recognition promptly.

The secretaries of the various sections of the Association should constitute an advisory committee to the director of the Scientific Exhibit. It would thus be possible in the preparation of the annual program to develop a co-relation between the work of the sections and that of the exhibit. Subjects of unusual interest in the sections might be illuminated by groups of specimens in the exhibit. A competent director would thus be able to render valuable assistance to clinicians as well as to those carrying on research work. It would further be the duty of the director to see that carefully prepared data were submitted with specimens and demonstrations; it would fall to him also to edit the same for publication and preservation in the archives of the Association. His energies would also be directed toward the establishment of a medical museum—a lasting monument to the work of the Association. Beside scientific exhibits it would also properly contain historical exhibits connected with the progress of medical science, especially in the United States. Under efficient direction such an institution would develop surprisingly. In a few years a commodious habitation would be necessary, but the growing wealth of the Association could easily manage that.

Future tendencies should be to condense and specialize the exhibit. It should be sought to illuminate certain phases of pathology. These might be varied from year to year according to tendencies in the medical world. The last exhibit was too cumbersome for systematic demonstration. The heterogeneous character of the material also militated against this end. With a collection half the size and specimens selected with a view to illustrating certain phases of pathology, demonstration of the exhibit would have been possible. Indefinitely greater would have been the advantages derived by visitors to the collection.

The Scientific Exhibit is in harmony with the spirit of the age which demands brevity; calls for facts rather than theories and deeds rather than words. Whether a specimen be presented in the exhibit of the American Medical Association, in the state medical society or in a county medical society the practical lesson taught and benefits derived are the same. Summed up, it is that a practical knowledge of gross pathology constitutes the most substantial basis for skill in diagnosis. The physician reading a paper, reporting a case or presenting a specimen is, to be sure, rendering a service to his colleagues. He confers on himself a much greater benefit. The knowledge begotten in the labor becomes a joy and a blessing to him like his own child.

The suggestion made at the meeting a year ago, that this be designated the "Section on Experimental Medicine," has suggested some observations. The dominant sentiment of the membership, no doubt, is that the work of the section should be directed along purely scientific lines, leaving all questions pertaining to the practice of medicine and surgery to other sections. There is not wanting ground to question the wisdom of such a course. In a section composed exclusively of specialists in pathology and physiology, may it not be that the good seed brought here will fail to be sown on the fertile practical fields of medicine, where it will best thrive and bring forth a bounteous harvest. Pathology and physiology

touch every practical branch of medicine in an intimate and fundamental way. This section possesses strong natural relationships and obligations to every other section. Every other section should receive from that on Pathology scientific light for guidance in the practice of the profession of medicine. Already, in this great Association, the rays of intense common interest have been focused on the Scientific Exhibit. It is becoming a luminous power for the dissemination of knowledge among the membership of the organization generally. In like manner this section should attract the progressive spirits from other sections, and so make itself felt through the strong arms of the Association.

Most deplorable, indeed, are the antagonisms prominently manifested now and then between pathologist and practitioner—to their mutual discredit and the hindrance of true scientific progress. A distinguished surgeon boldly denies that blood examinations, showing leucocytosis, are of value in determining the approach of suppuration. An eminent gynecologist asserts, with almost scornful emphasis, that the pathologist's report on uterine scrapings is valueless in the diagnosis of malignancy. These are but two instances of many which might be cited of eminent, aggressive and influential members of the profession harboring views which are erroneous and pernicious in their influence on the progress of medical science. They arise from failure to appreciate the true sphere of the pathologist as related to the clinician. Overmuch is expected of the pathologist. Improvements in the microscope and other instruments and means of precision in diagnosis have led to an exaggerated conception in the inexperienced professional mind of what they will reveal. Every pathologist of wide experience has often encountered the intelligent practitioner, untrained in microscopy, who, having failed by every other means at command to diagnose his case, now comes with assurance for its final and absolute settlement by the microscope.

Pathologic diagnosis has its limitations, and none appreciates this more than pathologists themselves. Pathologists are fallible, just as clinicians are fallible. What with numerous fledglings and the extreme difficulties of differentiation and pathologic diagnosis, errors are common enough. There is no intention to shield the errors of embryonic pretenders or the extreme claims of the pathologic sensationalist. Rare and yet to be found in our ranks are the conscienceless quack with beautiful drawings, fine phrasing and padded reports, as well as the crank and visionnaire, with his faulty judgments. It will be too much to hope that such will not find their way into the section. Most certain is it that there will be present in the membership more than a saving remnant of the elect of science, who will separate the wheat from the chaff, and strive always toward true and high ideals.

This section of the most powerful organized medical body in the United States should not only seek to preserve its scientific dignity and morale, but undertake the inauguration of practical reforms. It is within our province and becomes a duty to strive for the banishment of the antagonisms hinted at. Toward the accomplishment of so laudable an end the section officers should secure from eminent practitioners in the various sections occasional papers on practical topics with pathologic bearing. Contact of the man of pure science with him who applies scientific knowledge to practice, will tend to prevent narrowness and antagonisms on the one hand, and on the other prove conducive to harmony and mutual upbuilding. The mission of the physician is to minister to the suffering and heal the sick. Of this cardinal fact we as scientists should not lose sight. And on the part of clinicians there is need of appreciating more fully the great assistance afforded them by a practical knowledge of pathology and physiology. The great Virchow understood well the practical bearing of these subjects, when in a communication to the author concerning the Pathologic Exhibit he wrote: "I hope your countrymen will recognize the intimate relationship of a practical knowledge of pathology, not only to expert diagnosis, but also to successful treatment."

THE YEAR'S PROGRESS IN THERAPY.

CHAIRMAN'S ADDRESS, DELIVERED BEFORE THE SECTION ON MATERIA MEDICA, PHARMACY AND THERAPEUTICS, AT THE FIFTY-THIRD ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION, AT SARATOGA SPRINGS, N. Y., JUNE 10-13, 1902.

GEORGE F. BUTLER, M.D.

Medical Superintendent, Alma Sanitarium, Alma, Mich.; Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons.

CHICAGO.

The progress of therapeutics, materia medica and pharmacy during the past year has been neither startling nor specially important. The chief advances that have been made are based on the more stable ground of pharmaco-physiology, pharmacology and experimental medicine, rather than on any alleged specific therapeusis.

THE LOEB RESEARCHES.

One of the most prominent pharmaco-physiologic suggestions of the year has been Jacques Loeb's application of the physico-chemic notions of Arrhenius, Van t'Hoff and Oswald to pharmaco-physiology. If, as Arrhenius claims, it is the ion or chemical atom bearing its charge of electricity that acts, instead of the atom alone, and if this be the most potent factor in biologic processes, probably some type of electric energy can so modify physiologic forces as to act as an alterative in disturbed metabolism. This, however, is but a link in the chain of phenomena presented by cataphoresis showing that biologic forces are subject to the same laws as the ordinary physical forces. The experiments of the older physiologists show, however, that while analogous, heat, light and electricity differ in the character of their waves from the comparatively slow vital forces. The chemic forces, however, are nearer akin to the vital than the physical forces. Moreover, many of the vital effects attributed to electricity are due to the secondary chemic forces set in action by it. This was the opinion of the older physiologists, and has been lately corroborated by experiments of F. R. Zeit on the effect of electricity on bacteria, recently reported to the Chicago Academy of Medicine. The action of electricity as a primary force is coarser and more destructive than the chemic forces produced through such action. In dealing, therefore, with the influence of the ions, the acceptance of the old, crude notion of electric action is liable to result in error. Indeed, its assumed effect is in direct contradiction to the progress of evolution, which proceeds from the incoherent simple to the coherent complex with loss of explosive power. That there is an alterative action in light is evident, not only from the phenomena of photography, but also from the alterative action of the *x*-ray shown in *x*-ray dermatitis, as well as in its effect on cancer. This dermatitis belongs to the category of the dystrophic dermato-neuroses and not to that of the simple burn. Hence it is an expres-

sion of disturbed metabolism. The relation of the *x*-ray to static electricity illustrates how far electric action must proceed before it can be expressed as a biologic alterative. The experiments of Jacques Loeb (which have been cited as illustrating the identity of electricity and life) are simply one phase further in the demonstration of the value of the ovum in the production of life. All ova have a parthenogenetic tendency, which, as Boveri demonstrated at the last meeting of the German Society of Naturalists and Physicians, disappears through degeneration of the centrosoma. All that Loeb did was to show that this parthenogenetic tendency could be stimulated in sea-urchins by a normal salt solution. In certain infusoria the process of fecundation consists essentially in a subtle osmosis between the sexes. The experiments of Loeb did not create life, but simply stimulated bisexual generation at the expense of parthenogenesis. These experiments, therefore, demonstrate nothing as regards therapeusis.

There has been so much importance attached to the necessity of "bleeding into one's own veins" by agents which do not depress the heart that it is not surprising that this procedure should have been quite universally accepted and without question. Critical analysis, however, of the untoward effects of the agents employed demonstrates that their effects were produced through undue strain on the heart. Recent researches have shown that this undue strain leads to even greater cardiac weakness after pneumonia (in which these drugs usually were employed) than in cases of venesection. This is hardly surprising, since venesection would not have the local disturbing influences which the agents already described must have had. Their results again demonstrate the evil effects which half truths so often have exerted on therapeutics.

AUTOINTOXICATIONS.

Developments along the lines of autointoxication and the toxins have been a fertile source of therapeutic suggestion. The fact that delirium tremens is a toxic state, due to alcoholic saturation, with possible autotoxic results through interference with hepatic and renal functions, has led to a successful revival of the older system of treatment, which is practically venesection combined with an attempt to replace the serum of the blood by hypodermoclysis with normal salt solution. It is generally forgotten that the venesectionists of the centuries prior to the nineteenth endeavored to draw toxic substances from the system and introduce watery solutions of various kinds. Salt solutions were among those thus employed and were evidently suggested by the mingled success and failure of the operation of transfusion. Early in the clinical history of cholera it was found that one serious cause of collapse was reduction of the serum of the blood with consequent toxic results. Attempts to replace this by transfusion, while giving markedly good results, produced what were evidently thrombotic and embolic conditions. The replacement of blood by salt solutions had greater though more transient results. The effect produced by these during the first three decades of the nineteenth century are well described in the comments of the *Medical Magazine* of 1833. It remarks that "the warmth, activity and intelligence of health have been restored to bodies which a few minutes before were almost as . . . and ghastly as the tenants of the grave, and ease and even hilarity have been substituted for the mute and paralyzing agony of collapse. It has been shown that upwards of a gallon of saline injection may be introduced into the blood vessels in course of an hour without producing death or occasioning any disease."

The theory on which the saline injection was then used is thus given by Dr. Latta of Leith, Scotland, who was prominent in the advocacy of saline injections during the cholera epidemic of 1830. To continue the quotation: "The individuals most liable to cholera are those whose diet and habit of life are very apt to derange the function of the liver. The nature of the hepatic circulation is such as must render it very susceptible of obstruction when the blood is reduced to a viscid state by abstraction of blood serum and the nervous energy be blunted by the influence of any sedative. Hepatic obstruction prevents return of the blood from the bowels, producing the usual consequences of obstructed circulation—the effusion of serum. In other parts of the body the blood returns to the heart, flowing from branches to trunks, and when it reaches the center of circulation, it thickened from the draining effects of diarrhea. it collects as soon as the saline fluid is introduced along the veins, and then directly mixed with blood, free circulation is restored and congestion is removed from every viscus except the liver. There the circulation is widely different, the thick grumous blood gorges its venous ramifications and the obstruction thus produced must continue until by slow degrees it is penetrated by the more fluent circulating mass. Until this is accomplished diarrhea must continue. The symptoms of its restoration are cessation of the serous diarrhea and return of the biliary secretions." It must be remembered that this was written sixty years ago, yet in no small degree it anticipates the doctrine on which modern hypodermoclysis has been based. This method has all the advantages of venous injection without its dangers. On a theory very similar to that of Dr. Latta, Dr. Hopkins employed hypodermoclysis with marked success in the treatment of delirium tremens. The beneficial results thus obtained suggest its employment in the allied psychic states of the confusional insanities, which, whatever be the primary cause, are based on toxemic conditions. The furibund pathologic change in typhomania (the acute delirium of the Germans, French, Italians, Scandinavians and Russians, the delirium gravis of American authors and the Bell's disease of some alienists) forbids much hope of success from its use. The acute confusional insanities proper, however, present a most encouraging field for hypodermoclysis on the principles outlined by Hopkins.

SEROTHERAPY.

The theory of modifying the serum of the blood by remedies is an old one, and there have been two striking applications of this principle to serotherapy in modern therapeutics. One proposes to destroy the toxalbumins by sodium hyposulphite. This principle is an old one, but has failed because of improper methods of introducing the remedy. The modern methods are no more efficacious nor are they attended with less danger than the old.

Diabetes not unnaturally has some relation to sugar formation in the blood serum, and attractive therapeutic hypothesis based on this idea would strike the diabetic and acidiosic conditions as their fountain head by leading to sugar destruction in the blood itself. Trypsin, as Croftan has lately shown, has this faculty, and to some extent when normally formed in the body exercises an influence on sugar change. Croftan's attempts to control artificial glycosuria in animals by trypsin have proven, however, as he admits, rather disastrous. The

results in this phase of serotherapy have been so far merely suggestive rather than of actual therapeutic value.

The fact that toxins were met in the system by antitoxins and the advantage taken of this fact in the treatment of diphtheria has naturally led to the study of the relations of autotoxic states to antitoxins. The studies of the relation of immunization of certain venom to antitoxins have not unnaturally stimulated medical research as to the relationships of serum therapy to the nervous results of autointoxication. Epilepsy is admitted by the vast majority of neurologists to consist of a deficient motor inhibitory system and an autotoxemic exciting factor. Nearly thirty years ago Meynert claimed that behind the status epilepticus was the accumulation of a proteid toxic substance. The presence of this substance has of late been demonstrated beyond a doubt by urologic research. Accepting the principle of the relationship of the autotoxic substances to the autotoxic states Ceni has brought forward a number of very carefully conducted researches tending to show the influence of a specially devised serum on epilepsy. The results he has obtained undoubtedly favor the opinion that the principle is correct. The beneficial results of serum therapy in epilepsy are also evidence in this direction. The fact, however, must be remembered that too short a time has elapsed to accept the favorable results as permanent (considering that epilepsy always yields temporarily to every new treatment). There is very little doubt, however, that hematologic studies here, as elsewhere in disease, will be productive of results of great therapeutic value.

PHARMACOPEIAL IMPROVEMENTS.

The coming edition of the pharmacopeia will present features aligning it more with scientific therapy than has been the case in the past. The study of ointments from the standpoint of their therapeutic employment rather than their simple pharmacy is a step in the right direction. The pharmacopeia has hitherto, in its preparation, been swayed too much by pharmacal rather than by therapeutic requirements. The pendulum is now swinging in the right direction to the advantage of both pharmacists and physicians.

The recent investigations of Werthin of Ann Arbor and others on the hemolymph glands furnish a new suggestion along the line of chronic anemias, whether of malarial or other toxic states. The researches of Werthin have been somewhat modified by those of Morandi and Sisto, but their results are simply negative and not destructive of the position that under morbid conditions the hemolymph glands undoubtedly take on blood-forming functions. The discovery of the normal presence of arsenic in the thyroid has led to the addition of arsenic to thyroid powder in obesity and other conditions treated by thyroids. The organic salts of mercury are receiving considerable attention in the treatment of syphilis, the lactate being one of the latest developments of this line of research. The organic silver salts are likewise having their field of operation extended.

INVESTIGATIONS OF BLACK WATER FEVER.

The therapeutic relations of black water fever have been an interesting subject of discussion for the last decade and a half. The disease occurs all over the malarial belt, and in the southern United States has been considered an expression of malaria very frequently produced by the abuse of quinin. There is no doubt but that quinin sometimes produces, as Lewin long ago showed, hematuria without the existence of malaria. The observations of southern physicians found in the literature of a decade ago showed that abstinence from excessive quininization during hematuria reduced the bladder and kidney disturbance. Dr. E. H. Martin of Greengrove, Miss., pointed out ten years ago that in the treatment of malarial hematuria the urine must be cleansed preferably with turpentine and the bowels kept open preferably with the salines. For the malarial poison he preferred arsenic. Under quinin malarial hematuria is a terrible condition with a great mortality, frequent relapses, profound exhaustion and slow, protracted convalescence. Without quinin a much more favorable termination may be hoped for.

The researches of Koch and others on the African black water fever tended to corroborate Dr. Martin. Recently O'Sullivan Beare and others have demonstrated clinical phenomena tending to separate black water fever from ordinary malaria and charging much the same factors with its production as did Dr. Martin and other southern physicians ten years ago. O'Sullivan Beare has found that the fluid extract of *Cassia bergans* in doses of a fluid dram every two hours gives remarkable results in this disease. The value of therapeutic diagnosis has been singularly well illustrated in the distinction drawn between black water fever and malarial conditions.

The recent discussions of the cumulative effects of borax ignore the researches of Lewin, Folsome and others in the employment of this drug in epilepsy. Their observations show that borax has cumulative action when given in small quantities and long continued. These untoward effects are especially manifested on the gastro-intestinal canal, liver, kidneys and skin. They were so marked in the case of epileptics that the use of borax has been abandoned in consequence.

THE VALUE OF MATERIA MEDICA AND THERAPEUTICS.

The outline of pharmacy, materia medica and therapeutics just given has been intended to suggest that—in spite of the opinion of surgeons to the contrary—there has been regular progress in these sciences and, through their bearings on the great questions of anesthesia and asepsis, surgery has profited even more than medicine in the past, and seems likely to profit equally in the future. Medicine can succeed only as a unit, and surgery without medicine falls back into the hands of the victims of prurigo secundi, a disease no less prevalent now than when Verneuil called attention to it over twenty years ago.

Not only do many surgeons ignore the value of materia medica and therapeutics, but there can be found many medical men who advocate the abolition of the subject in medical colleges and the abolishment of the Section of Materia Medica, Pharmacy and Therapeutics in the American Medical Association. By rejecting therapeutics "the physician is nothing more than a useless naturalist," said Latour, "passing his life in discovering, classifying and describing human diseases. It is therapeutics which elevates and ennobles our art; it alone gives it an object; and I may add that by it alone can this art become a science."

What honest and unprejudiced physician can deny the value of the antitoxins, thyroid and suprarenal extracts, or the value of mercury, iodin, opium, arsenic, ergot, digitalis and strychnin, and of the anesthetics, antiseptics, antipyretics and hypnotics?

We know that such drugs as chloral, belladonna, physostigma, and nux vomica act on the tissues of certain parts of the brain and spinal cord, and thereby in-

crease or decrease the functions of those parts. We can depress the functions of the motor nerve endings with conin, and the sensory nerve endings with aconite. We can paralyze the involuntary muscle fibers directly with the nitrites, or indirectly by chloral hydrate, which depresses the functions of the vasomotor center. We can stimulate or depress the functions of cardiac muscle and dilate or contract the blood vessels. The tissues of the various glands may likewise be stimulated or depressed. We can improve the nutrition and therefore the function of almost all the tissues by iron, cod-liver oil and lime; and indirectly we can produce the same effect by the gastric tonics and digestives which promote the taking and absorption of food.

Dr. Albert Abrams, in a paper entitled "The Employment of Drugs in Diagnosis," alludes to the administration of certain drugs as a means of diagnosis. Amyl nitrite, for instance, relieves anemic headaches and intensifies those of hyperemic origin. Migraine of spastic origin is relieved, whereas paralytic migraine is aggravated. He claims that the phenomena of auscultation are in many instances brought out after inhalation of amyl nitrite. The antitoxins are of value as a means of diagnosis in diphtheria, cryptogenetic septicemia, hydrophobia, etc. Anesthetics are invaluable often in the examination of joints and to determine whether tumors, contractures, etc., are due to hysteria. Arsenic is of value in aiding a physician in the diagnosis of many neuroses. It is also an efficient aid in excluding tuberculous adenitis from Hodgkin's disease.

The diagnostic value of atropin in ophthalmic medicine is well known; colchicum in gout; potassium iodid in neuralgias, ulcerations, paralysis, etc., of suspected syphilitic origin, intoxication from mercury, lead, zinc, etc., and in actinomycosis; quinin in intermittent fever; salicylic acid in atypical manifestations of presumable rheumatic origin; salol for determining the motor activity of the stomach. Thyroid feeding constitutes an invaluable diagnostic means in the recognition of all cases of myxedema, whether the disease be the true form, sporadic cretinism or cachexia strumipriva. Thymol is especially destructive to the parasite of ankylostomiasis and is of undoubted value both as a means of diagnosis and cure.

Therapeutics implies more than the mere administration and local application of drugs. Climate and artificial aëro-therapeutics or medicated atmospheres are often important adjuncts in the treatment of disease. Balneology and hydrotherapeutics are immensely important and are increasing in popularity, and deservedly so. This subject alone requires our most careful thought and investigation. It is wonderful what results may be obtained by the proper use of water externally or internally, or both.

Equally important are the medical applications of electricity. No less an authority than H. Lewis Jones says there is no manner of doubt that electrical currents produce definite physiologic effects. The most obvious physiologic action of electricity is its power of stimulating living tissues. The metabolic activity of the tissues can be considerably increased by electricity, as Gautier and Larat have shown in their experiments on the elimination of carbonic acid gas and urea under electrical treatment, when it was found that an increase of 40 or 50 per cent. could be produced by general electrification.

Massage or "mechano-therapy" is another invaluable means of treating many diseases, particularly when applied by an expert. The practice of massage by people quite ignorant of medicine, certainly with no scientific training, and independent of proper diagnosis and directions from a physician, is altogether to be deprecated, and is one of the great sources of the prejudice against the method still existing in the minds of medical men.

I must not fail to mention "suggestive therapeutics." The fact that the condition of many patients is influenced favorably or otherwise by their mental condition is well known. Drugs are not all that is necessary in the treatment of disease, and one is a very narrow therapist indeed who seeks for no means of relief outside of a drug store. There are limits to the utility of drugs, and the want of belief in them is largely due to the fact that they are expected to achieve the impossible.

THE FUTURE OF THERAPEUTICS.

I believe with Brunton that the prospects of therapeutics are very bright. "I think it is highly probable," says Brunton, "that before long we shall have a series of drugs which will stimulate the biliary secretion of the liver or modify its glycogenic function, arranged in order of their comparative strength, in much the same way we now have the class of antipyretics. We may also fairly expect to obtain a series of remedies which will act on the spinal cord in such a way as to enable us to treat a number of diseases which are at present altogether beyond the reach of our remedies."

The grandest principles that challenge human investigation center round the subject of therapeutics. Let us master every phase of it, that we may be better enabled to relieve our suffering patients. It is to be hoped that the therapeutic researches of the present generation will be followed by yet more brilliant achievement and by its light the darkness of passing illusions be happily dispelled.

CARDIAC STIMULANTS.*

JOSEPH M. PATTON, M.D.
CHICAGO.

The group of drugs which in therapeutic nomenclature is included under the head of cardiac stimulants or cardiac tonics—the so-called digitalis group—has not yet, as applied to the treatment of cardiopathic states, been displaced by hydrotherapeutic, aërotherapeutic or mechanical therapeutic measures, efficient as these latter means may be. The great practical, as well as therapeutic interest, attached to this oft-discussed group of drugs is sufficient excuse for their present consideration to which this paper is limited. In this connection the terms tonic and stimulant have acquired a synonymous usage, a custom not strictly to be commended, because, while the principal cardiac stimulants have also tonic properties, and may correctly be so employed, there are certain well-recognized cardiac tonics, such as the iodids, which are not available for stimulant purposes. Again, the chief clinical application of this group of drugs is for the purpose of stimulating an incompetent heart. That these drugs exert a tonic effect at the same time is not forgotten; indeed, such an effect is postulated by efficient stimulation, but the former effect is incidental and secondary to the latter in the absence of which is not obtainable at first. Our dosage in the presence of evidence of failing muscle power, is

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, and approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

based on the stimulant properties of these drugs. The term stimulant, therefore, appears proper in this connection.

The one indication for the employment of this class of drugs is insufficiency of the heart muscle—a minus dynamic force with reference to the demand. The efficiency of these drugs may be modified by the nature of the specific cause of the insufficiency, which in certain instances may contraindicate certain members of this group. A relative insufficiency depending on increase in exocardial resistance does not necessarily indicate this group of remedies, or, if so, only in connection with agents which remove such peripheral resistance to blood movement. In some instances the latter agents are all that is necessary to allow the heart to perform its work, as was the case with a patient in whom considerable dropsy of the limbs and congestive enlargement of the liver were removed by five drops of tincture of opium thrice daily. In these cases such true cardiac tonics as strychnia or the iodids have their proper application.

It is not necessary at this time to discuss the physiologic action or the toxicology of these medicaments. The practical questions are, when and how to give them, and when to stop them. In some instances the latter question is more difficult to decide than the former, and imperfect results are often more due to faulty judgment on this question than to indecision on the others. The principles which govern the employment of the chief of this group—digitalis—also apply, with individual modifications, to the entire group.

DIGITALIS.

Digitalis easily maintains its position as the chief cardiac stimulant for general efficiency, reliability, and, numerically speaking, applicability. The indications and contraindications for its use have always been more or less in dispute, and probably will always constitute points of controversy. The limitation of Porter, who says that digitalis is useful only in lesions of the mitral valve, and there only for a short time, is too narrow. On the other hand, we may agree with Bartholow that the doctrine that digitalis is suitable for all kinds of weak heart is fallacious. Abstractly, the statement of Washburn, that broken compensation always demands digitalis, may be accepted in the sense that the one indication of its employment is dynamic insufficiency of the heart muscle without reference to the nature of the valvular lesion or other cause for such insufficiency. Practically, however, we find that individual causes of this insufficiency may so modify the effects of digitalis as to constitute a contraindication to its use. It is not necessary to say here that the mere presence of a murmur constitutes no evidence for or against the administration of digitalis, however frequently such evidence has been accepted. The real question rests on the inability of the heart muscle with respect to the presence or absence of features contraindicating digitalis. These features contraindicating digitalis may be due to intrinsic cardiac conditions, or may arise from causes exocardial in nature.

The cardiac conditions which may contraindicate digitalis are certain mechanical conditions of the heart, arising in consequence of valvular lesions, which operate as contraindications, even though the muscle may respond to the action of digitalis, also advanced degrees of myocardial changes. In the first class comes marked mitral stenosis, extensive aortic regurgitation and excessive degrees of aortic stenosis. Pronounced stenosis of the mitral opening contraindicates digitalis because of the overdistention of the left auricle during the longer diastole and, if the heart is slowed too much, the danger of the high pulmonary pressure causing pulmonary edema. Ewart points out that the drug should be at once suspended in these cases when the pulse slows down to 85 per minute, and that the rapid, irregular heart of these uncompensated cases is less likely to be mistaken for cumulative drug action because its danger comes at an early period from undue slowing of the heart.

Some cases of moderate stenosis, though, perhaps, with loud murmur, and many cases of double mitral lesion respond to digitalis better than to any other cardiac stimulant. The presence of mitral regurgitation is practical assurance of the safety of digitalis in cases with stenosis, while its absence should indicate caution in the use of the drug because of the danger of increasing too much the pressure behind an obstruction which does not lessen, and in a cavity whose walls have little resistance. According to Sansom, digitalis is often harmful in mitral stenosis by increasing ventricular action, which is not necessary on the left side, and results in overstretching of the right ventricle.

Aortic disease has been largely regarded as a contraindication for digitalis, especially regurgitation. According to Potain the latter condition is a contraindication unless the pulse is rapid. Peacocke states that digitalis is useful in uncomplicated aortic stenosis, and is generally indicated in double aortic disease, though there may be sudden syncope. The alleged pernicious effect on the left ventricle of prolongation of the diastole has been the basis of the complaint against digitalis in aortic regurgitation. Corrigan discouraged its use in his original memoir, and was followed by Fothergill and others. That this view as a generalization was not well taken is shown by the opinion of later authorities, such as Balfour, who says that digitalis or its congeners is imperatively demanded in failures from aortic incompetence, or of Broadbent, who says that the aortic cases with mitral symptoms should be treated as mitral cases. Washburn's approval is endorsed by Ewart with reservations, anginal pain being the main indication for its avoidance. He thinks digitalis dangerous in marked degrees of aortic stenosis except when there is acute dilatation with rapid running pulse. Groedel says that there is no indication that digitalis should be excepted in a whole class of valvular diseases, such as the stenotic lesions of the aortic opening.

When we consider the direct nature of the pressure in the left ventricle and its mechanical effects in aortic lesions, especially regurgitation in which dilatation is primary and progressive, it is not surprising that digitalis should be on the whole less effective than in mitral lesions. In the earlier stages of aortic lesions, when the heart muscle has stretched but is not markedly degenerated, we obtain relatively as good results from digitalis as in other lesions, but in later stages, when the muscle has degenerated as a result of imperfect nutrition, it is not reasonable to expect such results. We must remember that the hyposystolic period of aortic lesions, the period of the passive congestions that are so generally recognized as clinical evidence of the demand for digitalis, do not, as a rule, present until the heart muscle has undergone these degenerative changes to an extent sufficient to allow of stretching the mitral ring. If the drug fails here it is to be charged against the myocardial degeneration. And yet, even here we often have marked results which, unfortunately, are too

often but temporary because of imperfect coronary blood supply from imperfect filling of the aorta in the one case and too rapid emptying in the other. It is usually necessary to give relatively larger doses of digitalis in aortic regurgitation to produce effects, but the pulse reduction can not be safely carried to the same extent as in mitral lesions.

Acute myocardial inflammation, as a rule, contraindicates digitalis, always if extensive. According to Thompson, digitalis is absolutely excluded in acute degenerations of the heart. In many cases, however, of endomyocarditis of rheumatic origin digitalis, in suitable doses, may be of considerable service.

Chronic myocardial inflammations and degenerations present the most difficult class of cases in which to determine the eligibility of digitalis. The difficulty of distinguishing clinically between interstitial, granular and fatty changes is recognized by all clinicians and by some the differentiation is considered impossible. We are often obliged to adopt Huchard's plan of feeling our way with digitalis, even though we are inclined to be positive in our diagnosis. It is in this class of cases that various subjective as well as objective signs obtain a value as contraindications for the use of digitalis in vitium cordis of indefinite clinical outline. Potain says that myocardial lesions strongly contraindicate digitalis; that it may be dangerous, and that senile cachexia and fatty degeneration call for great care in using digitalis. On the other hand, Beates insists on the value of digitalis in the cardiac lesions of senility. Groedel says continuous small doses of digitalis are of use in slight fatty degeneration from alcohol and tobacco.

The presence of such extrinsic causes of relative or actual cardiac incompetence as atheroma, sclerosis of the vessels, or arterial spasm are by many regarded as contraindications for digitalis. Undoubtedly this is often correct, and yet if the heart be actually incompetent, even though it be through degenerative changes in the heart muscle, much good may be obtained by the careful exhibition of the drug. The argument is advanced that if the muscle has sustained degenerative changes how can it be expected to respond to the stimulating effect of digitalis? Very true, and yet we expect and obtain good results from strychnia and the iodids. Now if the circulation in and the nutrition of the muscle is good enough to respond to the tonic action of these remedies it will also respond to and be benefited by the action of digitalis, provided the latter be administered with due regard to the conditions present and its action be guarded by proper regulation of its action on the vessels. Clinically we often obtain remarkable results in cases where we have reason to expect failure, judging from our estimate of the heart muscle, and so one becomes impressed with the extreme difficulty of estimating the integrity of the muscle and the results to be obtained.

The large class of so-called muscular mitral insufficiencies are often much benefited by small and continued doses of digitalis in conjunction with strychnia and the iodids, and the action of the latter remedies are thus much enhanced, the above objection as urged by many to the contrary notwithstanding. Digitalis is of special adaptability in these cases because of the convenience of administration, the lack of stomach disturbance and the ease with which it may be administered in connection with vaso-dilators, cholagogues or laxatives. The doses of digitalis advocated by Beates in senile cardiac lesions present a startling contrast to the conservatism with which digitalis is administered by those who have less faith in its utility and who emphasize its dangers. He recommends 1/10 to ½ grain from 3 to 6 times daily if necessary, and, if dissolution threatens, ½ grain by hypodermic, repeated in an hour, and then ¼ grain by mouth every 2 hours till 2 grains are given. He claims that the blood tension is lowered rather than increased; that it can not be increased when the propelling function of the arteries is lessened, and that increased tension in old people does not contraindicate heart stimulants.

Recently, when recommending ⅛ grain of digitalis every 6 hours for a man 76 years old, I was asked by the attending physician to assume the entire responsibility of so doing. A few days later I found him assuming the entire responsibility of giving the same dose to the same patient every 4 hours.

When exocardial resistance to the circulation from general vascular disease is marked it has been generally accepted as contraindicating digitalis. Bartholow's statement that digitalis is justified when arterial tension is low may be taken as supporting this view. The same view is variously stated by many observers. Arteriosclerosis is not confined to the aged, is not always a general process, and the tension is not always increased. The heart may or may not be directly concerned in the general vascular changes, hence its incompetence may be actual or relative. In the latter instance the vaso-dilating remedies—the hypotensive medication of Huchard—have their most successful application. In the former instance a combination of this form of medication with heart tonics and probably stimulants is necessary. Digitalis as a vaso-constricting cardiac stimulant has been much objected to in this connection. If, however, degenerative changes in the heart have not progressed too far, digitalis combined with vaso-dilators is not only safe in most cases of vascular disease, but is markedly efficient. The best dilators are opium, nitrite of sodium and nitroglycerin. The latter is best for marked cases of vascular sclerosis with increased tension. Its fault is rapid and transitory action, developed in about twenty minutes and lasting about one hour and a half. Its administration in connection with digitalis should be delayed about three-quarters of an hour. Opium is an ideal dilator as regards reliability, length of action and adjustment of effects, but in many cases has its objections. Nitrite of sodium is reliable and without objection in this class of cases, barring individual susceptibilities. The relative quantities necessary to affect the vascular action of a dose of any preparation of digitalis equal to from 10 to 15 drops of the tincture would be, in the average case, of opium, 1/3 grain of powdered opium, from 3 to 5 drops of tincture, or 1/16 of a grain of morphia; of sodium nitrite, from 3 to 5 grains; of trinitin, from 1/200 to 1/100 of a grain.

In some instances other members of the group of cardiac stimulants will give better results in cardiac inability associated with vascular disease than will digitalis because of difficulty in modifying the vascular effect of the latter, or because it is not well borne by the stomach.

General symptoms contraindicating digitalis or indicating its suspension are, according to Potain, nocturnal delirium, pallor, cold extremities, trembling, and contracted pupils. Generally we find that intolerance of digitalis, or too large dosage, is manifested by sensations of oppression or disturbance about the pre-

cordium, dizziness, faintness, and, at times, irregular heart action.

The cumulative action of digitalis has long been a bugbear to its administration. Personally, I have never observed it, and I have been in the habit of giving moderate doses of the drug for from four to six weeks without interruption. Porter claims that cumulative effects result from interference with nutrition from the constricting action of digitalis on the arterioles. If so, the effective combination with vaso-dilators might tend to restrict cumulative effects. I have regarded these effects as the result of improperly selected cases or to faulty methods of administration. MacLaren thinks the toxic effect of digitalis is overestimated.

The best preparations of digitalis are the infusion made from the fresh English leaf, the tincture made from an assayed drug (Squibb's) and a reliable digitalin—such as Merck's digitalinum Germanicum. According to Arnold and Wood the latter preparation is stable and 1 grain equals 70 c.c. of the tincture of digitalis. Digitoxin is the most active as well as the most poisonous element of digitalis. Solomon says digitoxin is the chief ingredient of the leaves, is superior to digitalis as a diuretic and is more prompt and certain in its action in doses of from 1/1000 to 1/250 of a grain. Zeltner believes digitoxin to act better in primary cardiac disease and in secondary disease from emphysema and nephritis than digitalis leaves. He advises its administration by mouth, hypodermically, and by the rectum, and says there is no more danger from disturbance of the stomach or from poisoning than from digitalis. The latter part of this assertion certainly can not be accepted at present.

Digitalin (Merck) is a safe, reliable and eligible preparation. Providing its dose is properly adjusted and vascular effects properly controlled, its effects on the heart can not be excelled by other preparations of digitalis or equaled by other cardiac stimulants. Imperfect effects are generally due to too small dosage. From 1/12 to 1/8 of a grain represent, in the average case, a dose of from 10 to 12 drops of a reliable tincture. The extremes of life do not present the same susceptibility to digitalis that we are accustomed to allow for with other drugs. Jacobi has pointed out that children bear digitalis better and in comparative larger doses than adults. His allowances are: for an infant of one month, 1/10 adult dose; 6 months, 1/5; second year, 2/5; 4 to 14 years, 7/10. Early adult life generally presents more or less marked susceptibility to the action of digitalis. Old age requires practically as large a dose as maturity.

Continued administration of moderate doses of digitalis for periods of from three to four weeks, followed by interruption for like or lesser periods in order to obtain the full tonic possibilities of the drug, is a method whose value is generally underestimated, but properly carried out the asystolic period of chronic cardiopathics may be often considerably postponed. Groedel says that digitalis does not lose its effect by continuous use, and is useful in continuous small doses in heart lesions from overexertion. This method of using digitalis is particularly applicable in senile cardiopathics.

STROPHANTHUS.

Strophanthus, while a heart stimulant of value, is not to be depended on, in the presence of marked muscular failure, to the same extent as digitalis. It is valuable in regulating functional ataxia, or that due to mild degrees of muscular insufficiency. Its special clinical application is in relation to the latter condition in association with mitral stenosis. Here it is both safer and more efficient than digitalis except when there is dilatation of the right ventricle. Aside from a tendency to produce gastric disturbance it is well borne at all ages. The dose of the tincture (P. D. & Co.'s) is from 8 to 12 drops. It is best given in laurel-cherry water.

Fraser stated that strophanthus acted mainly on the heart and slightly on the arteries, which he considered an advantage, but which Balfour doubts, as the blood pressure is more variable and metabolism uncertain. The action of strophanthus on the heart is more transient than that of digitalis and its tonic effects are therefore less marked. Strophanthin fairly represents the action of the drug and is considered reliable by most observers. My own results have been best with the tincture when it was well borne. The dose of strophanthin is from 1/200 to 1/60 of a grain. The former quantity may be used hypodermically. The diuretic action of strophanthus is decidedly uncertain. In vascular diseases with relative cardiac insufficiency it often acts well when digitalis fails or aggravates existing conditions.

SPARTEIN.

Sulphate of spartein is valuable, both as a regulator of functional ataxia and as a stimulant in muscular inefficiency. It is adapted to the treatment of nervous irregularity in drug habitués. In myocardial weakness following acute diseases, especially influenza, it is useful. Its special field of usefulness, however, is in the continued treatment of various degrees of myocardial weakness and ataxia associated with myocardial degenerations of toxic origin, and in the various chronic degenerations which may be grouped under the head of senile cardiopathies. Voight thinks it indicated in weakness of the right heart. Thomas and Cushing, and Matthews think it acts directly on the myocardium. Heffron thinks it a reliable stimulant for weak heart walls. Chapman recommends it in dilatation of the heart, and in dropsy from dilatation of the right ventricle. The action of spartein is rapid and it may be used to sustain the heart until digitalis has had time to produce effects. The drug is soluble and may be used hypodermically. The dose of the sulphate is from ½ to 2 grains.

CAFFEIN.

Caffein has been recommended by Beaumetz, Huchard and Semmola in asystolic conditions, arrhythmia and cardiopathic conditions of bulbar origin as a cardiac stimulant and diuretic. In some instances it is efficient. It appears to be adapted to cardiopathic states associated with nephritis or with vascular disease, or both. In asystolism due to valvular lesions it is not, as a rule, effective, though it may be of use as a diuretic. In too large doses it causes dizziness, faintness and irregular pulse. Heffron recommends it in dropsy from parenchymatous nephritis when the heart is involved. Zenetz condemns it as having a poisonous action on the spinal cord, striated muscle and cardiac muscle like strychnia; as accumulating in action, of slow elimination (lasting from ten to fifteen days after last dose); as causing a slow rise in blood pressure, which culminates in cardiac and renal diseases, in from four to six days in symptoms of impending cardiac tetanus; and as showing marked individual variations as to the toxic dose. He thinks all renal or cardiac diseases associated with atheroma or arteriosclerosis absolutely forbid its administration.

Huchard is not afraid of the toxic effects of caffein, and recommends it when digitalis fails to act on a damaged myocardium, in cardiac weakness from infective diseases, and as superior to digitalis in renal diseases. I have employed it in cardiopathies of renal origin or association with good results, using a salt prepared by combining equal parts of the alkaloid caffein and sodium benzoate, two or three drams of each to three ounces of distilled water, giving a teaspoonful every six hours.

STRYCHNIA.

Next to digitalis, strychnia is the most useful of cardiac remedies. As a cardiac stimulant it is useful in the hypostolic period of all lesions, and is the only stimulant which can safely be used as such in connection with digitalis in any lesion at any stage. It is essentially the best stimulant when the right ventricle is overtaxed from rapidly developed strain. Its frequent hypodermic use is a most valuable means of stimulation in emergencies. The dose is from 1/25 to 1/15 of a grain. J. Basil Hall recommends large doses as a prophylactic against surgical shocks. He gave ¼ of a grain in two cases of impending death from air embolism with recovery. He thinks it futile in such cases to give less than 1/10 of a grain. Baumgarten thinks that in cardiac weakness the best results are obtained from small doses of strychnia, because large doses, besides having undesirable effects on the entire spinal cord by raising blood pressure, immoderately increase resistance to the heart's action long before it can assist it indirectly; that it must be used before the strength of the heart has sunk too low, because on Binz's statement that strychnia raises blood pressure by increasing reflex irritability of the vasomotor center, and not by stimulation, thus necessitating peripheral impulses to accomplish contraction of the vessels, strychnia must fail in the very conditions of collapse for which it is so much depended on; that moderate doses should not be long continued, because, like digitalis, it may accumulate. He charges clinicians with not being as well acquainted with the cumulative effects as physiologists and pharmacologists. Lauder Brunton says strychnia is a "cumulative poison," as it contracts the renal arteries and thus prevents its own excretion. A. H. Carter admits the utility of strychnia as a heart tonic for occasional use, but thinks its prolonged administration not justified except in the smallest doses.

The clinician is forced to deal with conditions of disease as he finds them, and is not always able nor does he always attempt to reconcile clinical results with physiologic argument—a privilege I will here avail myself of. The dosage of such remedies as strychnia must ever be a relative matter. I have administered strychnia continuously in 1/30 grain doses thrice daily for periods of from 6 to 8 weeks with results which I believe to be satisfactory in every respect. Also, I have given 1/15 of a grain hypodermically every 2 hours for 48 hours, and for 2 or 3 doses every hour, in critical collapse in pneumonia, with prompt response to every dose and final recovery. I have seen prompt and effective results from 1/10 of a grain in traumatic and surgical shock, and I am therefore not prepared to accept the second conclusion of Baumgarten.

Strychnia, in small doses, is the most valuable heart tonic we possess, and is particularly adapted to the treatment of senile lesions by continuous administration over periods of several weeks. During the second and third decades of life strychnia is not as well borne as it is later, being likely to excite and irritate the nervous system.

OTHER DRUGS.

Convallaria majalis, cactus, grandiflora, adonis vernalis, nerium oleander, coronilla scorpeoides are all cardiac remedies whose stimulant action is less valuable than those already considered. Canadian hemp has recently been recommended by Golubinin as a valuable cardiac stimulant. He recommends 5-drop doses of the fluid extract three or four times a day.

Suprarenal substance has obtained some use as a cardiac stimulant as would naturally follow from its effect on the vasomotor system. S. Florsheim says the drug acts quickly and causes rapid improvement in flaccid and fluttering hearts, arrhythmia disappears and the heart remains in better condition. The substance appears to have a tonic action on the heart muscle, causes more regular action, increased force and fuller, stronger pulse. Florsheim noted best effects in cases of dilatation with weak pulse, diffuse apex beat and fluttering, irregular action. Two cases showed contraction of the heart with stronger and more localized apex beat. I have employed adrenalin to raise blood pressure in conditions of collapse, and during the critical period of pneumonia when the blood pressure was low and the heart's action weak. In such instances the action of adrenalin is prompt and effective. Three or four drops of a 1:1000 solution may be administered hypodermically. As a cardiac stimulant the use of this substance has as yet been too limited to form definite conclusions as to its full clinical value or application.

DISCUSSION.

DR. HENRY BEATES, JR., Philadelphia—The phenomena of normal circulation depend on a relation of intracardiac pressure or tension with that of the blood vessels, and there also exists a constant relation between arterial and venous tension. I would lay down the rule that all lesions of the heart must be viewed from the standpoint of their being especially local, while all disturbances of the circulatory system, in which the one great result, disturbance of equilibrium, results, are due to either exocardial conditions, local and, frequently, influences operating from both. It is, however, the disturbance of equilibrium which all treatment is intended to overcome, and to restore lost circulatory equilibrium is the one grand object, whether it be by the use of so-called cardiac stimulants, or, as is sometimes necessary, the combined exhibition of these and sedatives.

In every lesion of the heart, there must be, for physiologic reasons, consequent exocardial change. This generally occurs in the arterial side first, and, sooner or later, in the venous also. When these two conditions obtain, the lymphatic disturbances next follow, and these require the observance of the same principle for successful treatment. It is these exocardial secondary lesions and the consequent inability for the disturbed equilibrium to be overcome that indicated, not the diminution of the dose of the cardiac so-called stimulant, but bold and heroic exhibition of increased doses. A moment's thought discloses the fact that, if the vis a tergo is greater than the vis a fronte, the heart feels no strain when its ventricle empties its contents into the aorta, and if it is weakened from a local lesion, there is not that intensified and fatiguing force necessary to be exerted, which adds to an already failing heart. But if the vis a fronte be much increased, it is necessary not only to give strength to the already tiring heart, but to remove the load from in front. There is not sufficient importance accorded to the part played by the arterial system in the work of carrying on the circulation of the blood mass. The importance of thoroughly appreciating the condition of the arteries is not comprehended by the profession generally as it should be, and it is only when the clinician will recognize that each artery is practically a heart for the part it supplies, there

will be a clearer understanding of the application of the principles involved, in the treatment of these conditions. When we give digitalis, or any other so-called heart stimulant (I prefer the term "circulatory" to "heart") we do not, by its administration, act alone on the heart but, let it be emphasized, on the blood vessels also (arteries and veins), and from what has been briefly said, it is evident that the object in view, being to restore equilibrium to the circulation, necessitates aid being given to the blood channels as well as to the heart. It is by this powerful influence on the vessels that digitalis proves so useful in these conditions. It removes the great load from before the heart, and enables the well-nigh exhausted viscus to pulsate, and thus digitalis saves life.

Referring to the mentioned cumulative action of digitalis, the somewhat extended studies of its derivatives lead me to the conclusion that these effects are due to the derivatives known as digitalin Belgic or chloroformique, and digitoxin; they have never occurred after years of continued exhibition of the use of digitalin Germanic Merck. I advocate, therefore, the use of that digitalin known as Germanic Merck. Another point: when any of the galenic preparations of digitalis are given, all therapeutic deductions which may be reached are necessarily unreliable. We know that any drug derived from the vegetal materia medica, in its crude condition, represents a feature characteristic of every vegetal organism. It is that principles or derivatives vary in their percentage presence and solubility; thus, one unit of digitalis leaves might represent 10 per cent. of this, 8 per cent. of that, 2 per cent. of the other, and so on, derivative, and these themselves vary in their percentage degree of solubility in alcohol, ether, chloroform and water. Indeed, some are insoluble in one or the other of these latter, and thus it is that tinctures, infusions, etc., cannot possibly represent a unit of therapeutic strength. The natural result, therefore, of galenic official preparation of digitalis, as well as the rest, is difference in clinical action. Digitonin is soluble freely in water, and hence the infusion contains this derivative in considerable quantity. The digitalin Germanic Merck is also soluble in water, therefore in the infusion we have a preparation that approximates a unit of strength, and for those rare conditions of disturbed circulatory equilibrium, where the action of the medicament is so pronounced on the vasoconstrictors as to produce local peripheral ischemias, and it is sometimes necessary to overcome this by the judicious use of a cardiac so-called sedative, and digitoxin possessing this property preëminently, we have, in the infusion, a very desirable remedy for this particular group of cases.

This point Dr. Patton has very clearly indicated, and brings forth the fact that there are conditions in which both stimulation and properly adjusted sedation may be required, and in these the infusion of digitalis answers a purpose second to none. Numerous cases are characterized by the cardiac musculature being weak, while the arterial tension is increased. In such cases, contrary to the usual teaching, digitalis is not only not contraindicated, but most emphatically demanded. It acts by restoring the propelling power to the arterial system, and removes from before the organically weakened viscus a great and almost insurmountable burden. In these conditions the preternaturally distended side of the circulation will rapidly disappear after full doses of digitalin Germanic Merck, gr. ½ from 3 to 6 times daily, in emergency cases, and a conspicuous great venous tension will, in the course of a few hours, disappear as equilibrium is restored.

DR. W. J. ROBINSON, New York—I wish to endorse what has been said about digitalin. There can be no doubt at all that the cumulative effect of digitalis must be due to some other agent than the principle digitalin. Disappointment in the use of digitalin is often due to the fact that the dose is too small; indeed, this must be so if we can give digitalin in doses as large as ½ grain three times a day, for days at a time, as we know has been done, and with good results. A prescription that I frequently use consists of 1/12 of a grain of digitalin, 1/60 of a grain of strychnin, and 1/100 of a grain of nitroglycerin. I have had patients take this pill for months without causing distress, or gastric disturbance, or bad results of any kind. I have found this combination a useful stimulant to the circulation, for prolonged use.

Among cardiac stimulants I would include camphor, the value of which is but little known in this country. The best method of administration is in the form of a solution (10 per cent.) made with pure olive-oil, to be given hypodermically. The usual dose of camphor is 1 or 2 decigrams (1½ to 3 grs.), or 1 to 2 c.c. (15 to 30 minims) of the solution. When this is given to a patient in a state of collapse the results are simply marvelous. In such a condition one or two hypodermics will produce most satisfactory results.

With regard to the use of adrenal substance as a cardiac stimulant, its effects are too evanescent for us to rely on it in cases of chronic disease of the heart.

DR. HEINRICH STERN, New York—I take exception to the statement that *Adonis vernalis* is inferior in the general run of cases to digitalis as a cardiac stimulant. I wish to know whether or not the author of the paper bases his opinion on personal experience with adonidin? Basing my conclusions on an experience with several hundred cases treated with adonidin, I maintain that adonidin is not a mere succedaneum of digitalis or its alkaloids, but that its action is in many instances markedly superior to that of the latter drug. Adonidin is more rapid in action than digitalin or digitoxin, and it may be given without hesitation in a number of instances in which digitalis or its preparations should not be prescribed, as a rule. In fatty degeneration of the heart, in various atheromatous conditions, etc., adonidin acts safely and efficiently. In rapidity of action adonidin excels most of the other heart remedies, as digitalin or digitoxin, strophanthus, spartein, etc. In certainty of action it is also superior to these drugs. It is more permanent in action than any of these medicines, without possessing the well-known accumulative properties of digitalis. It is especially useful if kidney disease is accompanying the heart affection. The diuretic qualities of adonidin in the normal kidney are little pronounced; it exerts very great diuretic activity, however, in conditions concurring with dropsy and low arterial tension.

DR. H. C. WOOD, JR., Philadelphia—With regard to the point made by Dr. Beates, I wish to confirm the statement that in the condition called "heart-failure" the heart is not solely at fault, the symptoms are due to circulatory failure. In such cases it is important to see that the vasomotor apparatus does its work. As digitalis acts also on this vasomotor apparatus, there arises a tendency in the minds of the profession generally to overestimate this action of digitalis and to avoid its use as a cardiac stimulant because it increases the resistance in front of the heart, so that the heart being compelled to act more powerfully and to do more work, the drug might fail to accomplish the purpose if the heart should be too weak to overcome the force in front of it. The use of digitalis in acute endocarditis has been advocated by some and condemned by others. In nephritis, we hesitate to give diuretics, because of their action on the kidney structures; but in endocarditis we do not hesitate to give digitalis, for its action is on the myocardium and not upon the endocardium.

With regard to the use of suprarenal extract, or adrenalin, it is to be observed that, when given by the mouth, it is too rapidly eliminated to produce any physiologic action on the circulation. In the laboratory it has been found that the only way to produce any effect on the circulation by this agent is to throw it into a vein. Even then the effect passes off in a few minutes. It is possible that suprarenal extract, or adrenalin, may prove of use in an emergency as a cardiac stimulant in very acute conditions, if used intravenously.

DR. S. SOLIS-COHEN, Philadelphia—The profession owes a great debt of gratitude to Dr. Beates for his patient insistence on the value of digitalinum verum, or Germanic of Merck. After becoming familiar with Dr. Beates' observations, I diminished my use of the common preparations of digitalis and used as much as possible the Germanic digitalin, which permits accuracy and regulation of dosage and is satisfactory in its results. Dr. Beates has also taught the profession that the dose of Germanic digitalin is not 1/60 grain, but more

nearly 1/6 grain, as the rule, and even much larger doses may be given with advantage and safety.

The point that Dr. Robinson mentioned deserves attention; and in order to be clear on the subject we must discriminate more closely between cardiac stimulants—temporary and quick in their action—and those drugs that have a sustained or tonic effect. When we wish to apply a quick spur to a flagging heart, we should give camphor or musk; for tonic action slowly developed and long continued we should turn to digitalis, strophanthus, adonidin, or spartein sulphate; while atropin stands between the two classes. Bartholow used to say to his pupils that we give digitalis to-day and get effects to-morrow. He taught that the stimulant effect of the tincture of digitalis given hypodermically was due to the alcohol rather than to the digitalis. This may have been an exaggeration, but it expressed his estimate of digitalis. The effects of spartein and adonidin on the heart are even more slowly developed than those of digitalis; while strychnin is the most prompt in action of the tonic class, especially as a vasomotor stimulant. The combination of strychnin, atropin and digitalin thus has a special value.

With regard to the suprarenal gland and its various preparations, after a rather extended experience I can not agree with Dr. Wood that when given by the mouth these agents are always inert. It is true that in many cases I have seen no result, but in some cases I have seen decided results which I could attribute properly to them. This might be the result of the method of administration adopted. My instruction to my patients is to allow the drug to dissolve in the mouth, and not to swallow it immediately. From observation of its effects on other mucous membranes, I am led to believe that effects on the general circulation can result from this manner of administration. A drop of adrenalin solution on the conjunctiva will sometimes produce a remarkable effect on the heart. I have made some clinical tests of the effects of this drug in various heart and circulatory disorders. In the Polyclinic and in the Philadelphia hospitals I have employed suprarenal extract in a large series of cases. In exophthalmic goiter it is frequently curative, as in certain types of cardiovascular asthma and albuminuria. In valvular disease of the heart, I have obtained little definite result. In a case of bradycardia, due to Stokes-Adams disease, of which I have notes of the autopsy, I administered suprarenal extract by injection into the conjunctiva; each injection being followed by transient increase in strength of the heart's action. This observation was confirmed by several other physicians who saw the case under treatment. I merely mention this experience to show that as yet the exact value of adrenalin in cardiac disorders has not been determined. We are in a position to say, however, that in some cases it will produce marked transient effects. I believe that when collapse seems to be impending, danger may be averted by this agent. It is certainly worthy of further study.

Dr. W. W. Tompkins, Charleston, W. Va.—The value of rest in cases of disturbance of the circulation and cardiac weakness is almost as important as the therapeutic agents just considered. It is of prime importance to lessen the work of the heart, and this can be done by rest; in the more aggravated cases absolute rest in the recumbent posture, in the milder cases relative rest obtained by reducing bodily activity. As to the form of digitalis to be used, it depends to a great degree on the idiosyncrasies of the patient. The pharmacopeia directs that its preparations shall be made from leaves of the second year's growth; and we are told that they contain nine alkaloids, each one exerting different physiologic effects. As far as my own experience goes, I regard the infusion as of most value, principally on account of its diuretic action. I think that in many of the cases of this character it is well to combine some form of iron with the digitalis, because these patients are generally very anemic. As a cardiac tonic, strychnia is most effective, and I frequently combine it with the digitalis and the iron. I believe, however, that, to a great degree, each case is a law to itself, and the method of treatment and the drugs employed must be selected according to the requirements of the individual cases.

Prof. C. S. N. Hallberg, Chicago—I wish to make a simple suggestion. Empirically, it is generally stated that there should be a distinction made between the infusion of digitalis and the tincture. The difference between the two preparations is unquestionably due to the fact that the active principles of digitalis are glucosids. Like all glucosids they are apt, in the presence of water, to decompose and to split into glucose and other principles, but in alcohol this does not occur and they retain their original character. This is of importance to pharmacists, as it bears on the question of the propriety of making the infusion from the fluid extract. The great difficulty with digitalis is—and we have the same with ergot—that sufficient attention has not been paid to this splitting of the active principles in the presence of water. We know that in the presence of water, amygdalin and emulsin in wild cherry and bitter almond form hydrocyanic acid, and that in many other glucosidal drugs there is probably a similar reaction, and that it is very important. In all these preparations of similar character, the method of manufacturing must have a great influence upon the therapeutic value of the product. The committee on revision of the pharmacopeia wished to make a standard for the preparations of digitalis, but found it impracticable to do so. Our knowledge is not sufficiently advanced at present to permit this to be done. It is the same with ergot. I mention this fact in order to indicate the necessity for a more thorough knowledge of the constituents of these plants, so that their active principles may be of more uniform potency and strength.

Dr. Jos. M. Patton, Chicago—The point of Dr. Beates on the pharmacodynamic relations between disorders of the circulation, diseases of the heart, and digitalis, was explained in a lucid manner. The opinion has been expressed that digitalin is a safe, reliable and effective agent in relatively large doses and the statement made that it can be given in such doses for a considerable period of time, in appropriate cases, without danger. I concur in this opinion, but think that patients should be kept under careful observation, when such unusual doses are given.

In reference to the remarks about camphor, in my paper I did not take up that class of remedies but only the direct cardiac stimulants. In cases where a prolonged effect is required, we use digitalin because its action is more sustained. It not only increases the power and action of the heart, but keeps it up. If we wish to have only a temporary stimulating effect we use ammonia, alcohol or some other article of that class; but for a sustained effect we give digitalis.

In reply to the gentlemen who spoke of *Adonis vernalis*, my paper was confined to the statement of the results of my own experience, and I have had no experience with adonidin. I feel satisfied, however, that where a heart-muscle is degenerated or weakened I can not get the results from adonis that I can from digitalis. My experience does not confirm the claim that has been made on behalf of other drugs that were said to be as good as digitalis, although I would be very glad to have something as valuable as digitalin to use in the class of cases needing a heart tonic. I confirm the remark of the gentleman from West Virginia about adjusting our remedies to suit the individual case. He was also perfectly correct in saying that rest is one of the most important cardiac remedies. There is no reason, however, why the infusion should be different in its effects from other preparations of the drug, if the others are given in corresponding dosage. In some patients the infusion is preferred, in others the tincture may be more suitable. Personally I have been in the habit of relying on the digitalinum verum for the reason that it is reliable. It also agrees with the stomach better than the other preparations and the dose can be regulated more accurately to suit the needs of the case than any other form in which this remedy can be administered.

Ice for Respiratory Hemorrhages.—Ice applied to the external genitals—the scrotum in men, the labia in women—is said to the best and simplest method for controlling blood-spitting and nose-bleed.—*Canada Medical Record.*

ADENOIDS.*

W. FREUDENTHAL, M.D.
Consulting Laryngologist to Montefiore Home, Beth Israel Hospital, and Bedford Sanatorium for Consumptives; Laryngologist to St. Mark's Hospital, Etc.
NEW YORK.

About seventeen years ago, when I came to this country, after having seen and operated on many cases of adenoids at Berlin and Freiburg, at one of the first meetings of the New York Academy of Medicine which I attended, a prominent colleague made the remark that while there might be found such things as adenoid vegetations among the children in Denmark or in Germany and Russia, the Anglo-Saxon race was free from that anomaly. In the years that have elapsed, I am confident that the gentleman has been convinced that they do exist in England as well as in the United States, and nowadays I have yet to see the practitioner who has not encountered cases of so-called adenoids in his own practice. They have been, so to speak, part of my daily bread for more than eighteen years in clinics and private practice. Still, when your Chairman did me the honor of asking me to read a paper before this Section, I was somewhat embarrassed as to what to say to a body of experienced practitioners that would be new to them on this topic. The libraries abound in articles and pamphlets on adenoids, which for some time have been viewed, not as a curiosity, but as an every-day occurrence. They have become so frequent in all parts of the globe that every practitioner must of necessity be familiar with them.

Adenoids grow in a place which I long ago considered the most important of the whole breathing apparatus, viz., the retropharynx. We can and do examine easily all other parts of the upper respiratory tract, but the retropharynx, which is the *locus minimæ resistentiæ* for many a disease, is too often overlooked. No wonder that adenoids, which have existed as long as civilization, were overlooked, and discovered only as late as 1868 by Wilhelm Meyer of Copenhagen. It is undoubtedly true, however, that Voltolini removed them already in 1865 with the galvano-cautery without recognizing their importance.

Now, what are adenoids, or, as they are also called, adenoid vegetations, adenoid growths, pharyngeal tonsil, third tonsil or Luschka's[1] tonsil? We had known since the time of Morgagni that the parts in question belonged to the tonsillar tissue, but only through the works of Henle, Kölliker and His have we acquired a thorough microscopic knowledge of these structures. It was my former teacher, Prof. Wilhelm His of Leipzig, who called it adenoid tissue, and since then the name adenoids has become so popular that we can no longer change it. Waldeyer showed that the adenoid tissue in the upper pharynx is only a part of a lymphatic pharyngeal ring ("lymphatischer Rachenring"), which now goes under the name of Waldeyer's ring.

Any part of this ring may undergo acute and chronic changes. Just as the faucial tonsil may become the seat of acute and chronic inflammation, the pharyngeal tonsil may be similarly affected.

ACUTE CATARRHAL INFLAMMATION OF THE PHARYNGEAL TONSIL.

This is called by the French adenoiditis, with which most likely the *fièvre ganglionnaire* is identical. It is not as infrequent as is ordinarily believed, for, according to my experience, it often occurs in young children. As an examination is difficult or often impossible the diagnosis is very seldom made. A digital exploration should be omitted, if possible, on account of the reactionary inflammation and pain following this procedure. The main symptom of an acute adenoiditis is earache. It is sometimes very severe, and as there is pain in swallowing at the same time, the child refuses all food and runs down quickly. Frequently the child pulls on the ear, and this is taken either as a diagnostic sign of teething or of an acute otitis media. I have examined the ears of such children, but found nothing pathologic there, and the whole process subsided without affecting the ears at all. This, unfortunately, does not always occur, for pus forms not infrequently, as you all know. But this happens mostly after or in connection with an acute adenoiditis.

In other cases the sound of the voice is muffled and the breathing difficult, which again is regarded as "a cold in the head." Here the examination of the nose reveals nothing, except perhaps a slight hyperemia of the mucous membrane. In grown children the pain in swallowing is very characteristic, and resembles very much that seen in cases of tonsillar or peritonsillar abscess. In my cases fever has always been present, sometimes as high as 104 F.

If there already exists a hypertrophy of the adenoid tissue in the vault of the pharynx, then the tendency to acute inflammation is so much the greater, just as with the faucial tonsil.

THE TREATMENT OF ACUTE ADENOIDITIS.

The treatment which has given me the quickest and best results is the following: First evacuate the bowels and put the child in a hot bath with some mustard in it. Then give small doses of quinin, or aspirin, or salicylate of soda, and order inhalations of the normal salt solution or of some aromatic oils every two or three hours. Sometimes I direct a few drops of adrenalin (in the proportion of 1:6000, 1:8000, or even 1:12000) to be sprayed or dropped in through the nose, of course, warm or lukewarm. This can be done every few hours according to the age and condition of the child. A Priessnitz compress around the neck over night is sometimes of great service.

I will omit here the acute follicular and the acute phlegmonous inflammation of the pharyngeal tonsil, and come now to the well-known chronic form.

HYPERTROPHY OF THE PHARYNGEAL TONSIL.

As a matter of fact, this affection ought to have been recognized one hundred or more years ago, if some one only had had the idea, that apparently is not too far off of applying digital examination of the retropharynx in cases of obstinate nasal obstruction. By digital examination alone has it been made possible without any special skill to generally recognize the hypertrophy of the pharyngeal tonsil so very frequent among children. Surgical operations with cutting instruments in place of the inconvenient and difficult galvano-cautery operation has opened the therapy of this affection to the whole medical world (R. Kayser). It is important that this has been finally accomplished, since no single affection in the whole domain of medicine and surgery has so far-reaching an influence on the public health as these "innocent little overgrowths," as Dr. Francis[2] called them. I should rather call them "nocent," knowing what harm they can do. When we consider that Max

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Diseases of Children, and approved for publication by the Executive Committee: Drs. H. M. McClanahan, Edwin Rosenthal and Samuel W. Kelley.

Schaeffer,[3] twelve years ago, found among his 1,000 cases of adenoids that in 467, or in almost 50 per cent., the ear was involved, and that William C. Braislin[4] concluded in 1900 that ear diseases almost invariably accompany adenoids, we have no right to call these growths innocent. They have done an immense amount of harm. "But by sheer weight of evidence, practitioners of medicine, parents and others who have to deal with the young, have at last become convinced of the practical importance of the discovery, with the result that many cases which forty years ago would have been allowed to lapse into hopeless deafness, or to fall victims to all the baleful consequences of neglected middle-ear suppuration, are quickly recognized and relieved."[5] These last remarks were made by Yearsley only a few months ago. When we analyze statistics, however, we must ask ourselves: Are these little overgrowths on the increase among children or not? It seems to me that it is a difficult matter nowadays to find a city child without adenoids. There is, to my knowledge, no difference as regards climate, race or sex. No race is exempt from them, and while we formerly believed that they were more prevalent in damp or cold countries, we now know that this was a fallacy. In all countries, whether warm or cold, dry or moist, adenoids prevail, and they occur *ceteris paribus* in about the same proportions. The cause of their existence in such enormous numbers is due to our modern mode of living, to the poor and faulty hygiene that surrounds our children. But what special agent is at the bottom of it? Is it the housing of our young ones; is it the simply appalling neglect of all laws of hygiene in our public and private schools, not to mention the "kindergartens"; or is it something else? Many of our kindergartens, indeed, deserve much more the name of pest-holes than that of a "garden." A "kindergarten" in a low, overheated, ill-ventilated room, as most of them are, is a menace to humanity. Frœbel would turn around in his grave if he were to see what sort of hygienic methods we apply to the growing generation. And most of the other schools are no better. These, indeed, are the most favorable conditions for developing catarrhal inflammations of the upper air passages, as I have attempted to prove elsewhere. These inflammatory processes of the nose, and especially of the retropharynx, are the first consequences of the evils just spoken of, and on the basis of these "catarrhs" adenoids develop. They are nothing but the products of a reactionary inflammation, which sets in easily under the influence of various causes. If, for example, such a child is infected with scarlatina, measles, diphtheria or other diseases affecting the upper air passages, the already existing "catarrh" is very much exaggerated, and then, as happens so often, we have adenoids following almost immediately these infectious diseases. Such children are sometimes brought to me for the removal of their adenoids, at a time when I consider it too early to operate, being afraid that the infectious germs have not yet left the air passages. To give you an illustration: A child came to me two weeks after it had recovered from a pronounced attack of faucial diphtheria, and as the Klebs-Loeffler bacillus has been met with at a much later period in such cases, I thought it possible that a new infection might be stirred up by the operation, and therefore postponed it.

Even tuberculosis can make its primary entrance through the retropharynx, as I proved some six years ago. It is evident that the organism frequently reacts against the invasion of tubercle bacilli and hypertrophy of the lymphoid tissue at the vault of the pharynx is one of these evidences. There is no doubt that tuberculous infection of the adenoid tissue is found only exceptionally, and the reason for this is that the mucous membranes of the head, as has been shown by Bollinger, manifest a marked tendency to allow the tuberculous virus to pass through their structures without themselves becoming diseased. And this quality is considerably enhanced by pathologic and especially inflammatory changes of the mucous membrane. Thus we can understand how the tubercle bacillus will penetrate even the intact mucous membrane. But what becomes of it? No doubt when it penetrates into the deeper tissues its passage is followed by a reaction, the result being adenoids in the first instance, and then, lower down, swellings and suppuration of the glands of the neck. That these lymphomata colli are in direct connection with the adenoids is demonstrated by a case like the following:

Case 1.—N. McC., twelve years of age, was brought to me from Newark, N. J., with a lymphoma colli. I opened it, removed a quantity of pus and all diseased tissue and sent him to the mountains for four months, where he was under the best care possible. The boy had slight adenoids which I did not remove at once, as the parents would not give their consent. The wound did not close, and finally, after three months more had elapsed, I operated on the adenoids, with the result that within two weeks the wound of the neck had healed thoroughly. The boy is now in his seventeenth year and well and strong.

I am under the impression that since adenoids are removed so freely, glandular swellings of the neck have become more rare. I am not positive whether further statistics will verify this.

If, for some reason or other, the path of the tubercle bacillus downward is closed up, by adenoids or other causes, it makes its way to the cranial cavity, where a tuberculous meningitis, so frequent among children, is set up. This idea of mine is as yet only a theoretical deduction which I can not prove, but which seems very plausible to me. In an interesting paper read before the International Medical Congress at Paris, 1900, Dr. Paul Gallois spoke on infection through adenoids. He also believes that they are not only the seat of primary infection, as tuberculosis, etc., but that they are apt to spread various infections to the neighboring and remote parts of the organism. Thus, for example, many cases of infectious sore throat result through adenoids; rheumatism in different parts of the body also has its primary origin in the retropharynx, the seat of these little growths. This is a point which I mentioned some time ago. We have come to recognize the fact that articular rheumatism often gains access to the system through diseased tonsils. While this may be true to a certain degree, I have always, and still do, attribute the more important rôle in this respect to the retropharynx. We see the tonsils, but we do not see the retropharynx, that is to say, in over 50 per cent. of all cases it is not examined, and therefore overlooked. Adenoids only help to make it the *locus minimæ resistentiæ.*

Normally with the establishment of puberty an atrophy of the pharyngeal tonsil sets in, which B. Fränkel called the physiologic involution. This involution also takes place when the adenoid tissue is hypertrophied and has not been removed. One of the results of this is the familiar form of postnasal catarrh; another the cicatricial process known as Tornwaldt's disease. Schwabach has shown that what is called by Tornwaldt the bursa pharyngea, was perhaps nothing else than the median recess of the pharyngeal tonsil. On

the other hand, Lehmann has described a congenital cyst of the bursa pharyngea. There can be no doubt however, that the bursa itself is an anomalous structure, as has been demonstrated by Mégevand, Max Schäffer, Jonathan Wright and others. It must surely be of rare occurrence, since it has been observed by so few authors.

As the time allotted me has nearly expired I shall discuss only a few additional points. To speak before such a society as this is, of the symptoms, diagnosis and effects of adenoids on the ears, eyes, respiratory tract, abdomen (hernia[6]), and on the system at large, would be to carry coals to Newcastle. All this is so well known that I believe it to be the common property of every practitioner.

Let us rather discuss the questions: 1. When shall we operate? 2. How to operate? And 3. What are the after-effects and after-treatment?

WHEN SHALL WE OPERATE?

As these growths make their presence felt from the first weeks of infancy we sometimes have to operate very early. The youngest child that I have operated on was seven months old. In this case there was a stubborn mucopurulent discharge from the nose that did not yield to any treatment, and as the whole postnasal space was filled with adenoids the child took nourishment with great difficulty, did not gain in weight, but was losing ground constantly. All these symptoms improved after removing the adenoids. Still, I do not like to operate on children under 2 years of age, as almost all the reactions I have noted after these operations were in infants under 2 years. I could not always explain their occurrence satisfactorily. In older children I can not recollect having witnessed fever of any account. But I will admit that I have not examined my books with a view of elucidating this point. To go through all my private records and clinical notes for this purpose would mean an immense sacrifice of time, which I did not have at my disposal. Let me narrate some of these instances:

Case 2.—M. S., 15 months old, was operated on at 8 a. m., May 16, 1887, for simple adenoids. In the afternoon the child was restless, refused all nourishment and felt "very hot." My assistant found an elevation of the temperature of 106 F. at 5 p. m. As I was out of town, I did not see the child until the next morning, when the temperature was perfectly normal. The child recovered quickly.

Case 3.—Another case was that of H. K., 13 months old (adenoids—otitis media purul.—mastoiditis). A colleague in this city had advised removal of adenoids prior to the mastoid operation. The parents consulted me, and I coincided with his opinion. On Feb. 16, 1894, I removed the adenoids under chloroform. February 18, the child had a temperature of 104.2 F., profuse discharge from the nose and ear, was restless and took no nourishment. There was a good deal of edema of the uvula and the neighboring parts, which I directly ascribed to the operation. The manipulations with the curette were sufficient irritation to produce the edema in this delicate infant. There were no other signs of a reaction. The high temperature persisted for three days, when it became normal again. The discharge from the ear ceased completely two months later, and there was no longer any indication for operating on the mastoid.

I was under the impression that in this case the infection was carried from the ear to the retropharynx. As the result was so excellent I should not hesitate to take the risk in similar cases. On the contrary, I consider any danger arising from the ear, and the inability to take sufficient nourishment as positive indications for removing the adenoids, even in very young infants.

When, however, we have an infant with adenoids that breathes comfortably, sleeps restlessly only when it has a "cold," has no ear complications, and takes his food properly, I invariably prefer to defer the operation until the child is 2 years old or more.

When the child is older, shall we operate whenever we find a hypertrophy at the vault of the pharynx? By no means. Slight hypertrophies are so common that they can hardly be called deviations from the normal, and to operate in such cases is, to say the least, unnecessary. But, unfortunately, it is done, and like every other procedure that has proved of benefit, it is overdone nowadays. "Many a pharyngeal vault is scratched because it contains a perfectly normal amount of lymphoid tissue, and the child is really suffering from the vasomotor results of too much candy on the stomach, or of too much clothing on the back, or of too much coddling in steam-heated houses." (Jon. Wright.)

Fifteen or twenty years ago there was need of encouraging the performance of these operations, as the majority of practitioners were more or less afraid of handling adenoids. Naturally enough many cases were neglected at that period. Nowadays it is better to sound a word of warning in the other direction. I know that too much operating is being done already. I could narrate many interesting instances of this kind coming under my observation, were I not limited in time. Not every child that snores, or keeps his mouth open, has adenoids. There are other things under the sun which we can and must treat!

In spite of this, there remain thousands of cases where we absolutely have to remove the adenoids. When a child is brought to us with adenoids which even only partially close up the choanæ, or where an affection of the ear coexists, not to speak of all the other well-known lesions that occur as sequelæ of adenoids, then I advise the parents that an operation is absolutely necessary and that its omission is a very risky and perhaps dangerous matter for the child's health.

Let me remark, apropos, that I have not had the courage to operate in hemophylics, of which four cases came under my care.

THE OPERATION ITSELF.

When we do operate, we must not forget that we have here to deal with a field that is already infected. No amount of antisepsis will do any good in these cases, but they are liable to do harm. My views on this point have not changed for the last fifteen years, viz., that a strict antisepsis is impossible and unnecessary. And this is much more true of the retropharynx than of the nose.[7] To wash out the mouth and throat with any antiseptic solution will be found bacteriologically entirely useless. The contact of the fluid with the mucous membranes is too short to kill even one bacterium. To wash the face of the child with an antiseptic or alkaline solution before the operation is playing with antisepsis, and syringing the nose before operation is dangerous.

For general anesthesia I invariably use chloroform, and am glad to be in accord with Sir Felix Semon and W. Williams.[8] The few times I have given ether or ethyl chlorid I was not pleased with the narcosis. Still, I must admit that there are many with wide experience who prefer either of these two.

In what position shall the patient be placed during the operation? For several years, i. e., from 1887 to about 1893, I used the upright position, recommended again lately by T. R. French[9] in a very instructive paper. I have given it up again: firstly, because in older chil-

dren it was not very convenient, although I must admit that at that time I did not have Dr. French's chair, but an arrangement of my own; secondly, because I encountered a few times unpleasant accidents which were due to the upright posture. I remember one case, a boy of 14, without any cardiac lesions, where breathing stopped for a while, the pulse became very feeble and I had to work for about two hours in order to thoroughly restore these functions. Similar, though not marked accidents have happened in several other instances, so that I came to the conclusion that the danger of anesthesia in the upright position was well founded. Nor do I favor the so-called Rose's position, i. e., with the head of the patient drawn over the edge of the table and bent well back. I am under the impression that the severe hemorrhages that have followed operations in this posture were indirectly caused by it. The surgeon is more apt to cut deeper into the normal tissue and wound a larger vessel, as the parts are more exposed.

Without any previous preparation, as douching or syringing, etc., my patients are put on a table, lying on their backs, the head not being raised and only a small pillow placed under it. The chloroform is given "slowly and cautiously and not pushed to the abolition of the cough reflex which protects the larynx against the entry of blood (*loc. cit.*, p. 720). The operation is performed thoroughly, which means all pathologic growths are removed and not a particle more. We "shave the surface clean" and no more. The attempt to remove all adenoid tissue will only be made by those who forget that we normally have and need such tissue. I have seen the operation done so "thoroughly" that I was convinced that the greater part of the mucous membrane was removed at the same time. On the other hand, there is often found a mass of thickened tissue at the lower edge of the growth, just below the velum, and I agree perfectly with French that this should always be well removed. A failure to do so is invariably followed by incomplete restoration of nasal breathing.

AFTER-TREATMENT.

As mentioned above, no preliminary antiseptics are used. If the patient bleeds during the operation and the blood flows through the nose and down the pharynx, this is the best antiseptic we could wish for. At the same time the flow of blood brings away masses of pus and purulent matter that have accumulated there for long periods. My after-treatment consists in keeping the child quiet for a day or two and giving it a carefully selected diet. The application of a nasal or postnasal douche I consider dangerous right after the operation.

Now, some children will not lose their nasal or postnasal catarrh after the operation, and the most important after-treatment has to commence then. I prefer to perform these operations in the spring, so that the children can stay, if at all possible, a few months in the country, preferably in the mountains. I have had excellent results in these cases, although naturally I have had to operate during all seasons, and with good results, too. In other instances, we have to treat the nasal catarrh systematically. If this be neglected, and it is neglected often, then a relapse of the adenoids will surely follow. In six months or a year we will have the same amount of adenoid tissue as before, in spite of the fact that they had been removed thoroughly. In very old and neglected cases we sometimes find hypertrophies of the turbinals which do not recede after the operation. In such cases, which are nothing but *stasis hyperemia*, the galvano-cautery was formerly used. I warn against such a procedure, as atrophy of the nasal mucosa will often follow. The congestion that is present ought to be removed by treating the postnasal catarrh with all perseverance possible. Among the different factors in the management of adenoids none is of greater importance than the treatment of these nasal and postnasal catarrhs after operation, and by persistent efforts in this direction I am sure that we will obtain still better results than have been achieved heretofore.

I trust these brief remarks will bring out a full discussion which will prove of benefit to all of us, although I am fully aware that I have touched on only a few points of this extensive and important subject.[10]

Dr. Semon deals here extensively on adenoids and I appreciate that we agree on most points. His remarks are so excellent and touch in a broad sense on so many questions that I believe every practitioner ought to read this booklet.

CHLOROSIS.*

C. F. WAHRER, M.D.
FORT MADISON, IOWA.

ETIOLOGY.

This affection is, with very few exceptions, confined to the female sex, and that principally during adolescence, usually heralding some disturbance of menstrual function, but chiefly characterized by deficiency of hemoglobin of the blood. It seldom affects early childhood, and if so, is usually connected with precocious development of sex. It is also seldom seen after the thirtieth year, but is by far most common at the beginning of puberty. It is also claimed to be at times hereditary, or apparently so. Sedentary occupation, indoor life, unsuitable food, excessive physical and mental activity, emotional or psychic disturbances are all causative in the majority of cases of chlorosis. It is remarkably frequent in girls who menstruate prematurely, indeed, one can usually predict a case of chlorosis in girls whose first menses appear very early. Often this affection is associated with anemia, coexisting or following soon in its wake. Careless observers may make a mistake in diagnosis, though this is one of the most easily diagnosticated of all diseases. These patients are often plump, even fat, or may be plethoric, making a striking contrast to the various cachexiæ for which it is sometimes mistaken. It is never due to menstrual troubles; these may follow, not precede or cause chlorosis. Nor does it ever give rise to tuberculosis, as popular fallacy teaches, but the reverse is exactly true, although at times it follows long protracted sickness and wasting discharges.

The worst cases we find among factory girls in large cities, for obvious reasons; however, it is not rare in all

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Diseases of Children, and approved for publication by the Executive Committee: Drs. Edwin Rosenthal, H. M. McClanahan and Samuel W. Kelley.

conditions of life. As far as race is concerned, we find it to preponderate by far among the white race. Constipation is usually present, and precedes the affection, as also do gastrointestinal disturbances and anorexia.

The chief causes are sex, puberty, predisposing constitution and, perhaps, heredity. The exciting causes are often anemia, insufficient and improper food, poorly lighted habitations, mental and physical overwork, grief, worry, anxiety, nervous excitement, sometimes cold and constipation, producing an auto-intoxication, gastroptosis and enteroptosis, these last two being usually brought on by tight lacing.

SYMPTOMS.

The appearance and symptomatology of the patients are characteristic, so much so that an experienced physician usually makes his diagnosis by inspection, of course supplementing the same by careful examination, not forgetting in difficult cases a blood examination for the estimation of hemoglobin, which is always deficient, often as low as 30 per cent. and even lower. Hence these patients are pallid, especially cheeks, ears and lips, also conjunctiva. We also note a yellowish white or greenish white tint, hence the name chlorosis. When blood is drawn it is often so pale as to scarcely show any red color, and an easy test is now made and a fairly correct one by means of the Tallquist hemoglobin scale, in which various degrees of red indicate approximately the percentage of hemoglobin present. This device is in booklet form and all you need do is to stain one of the sheets with the patient's blood and compare with the scale to make your estimate, which for clinical purposes is sufficiently correct. I need not draw your attention to the more difficult method with the hemoglobinometer, which, though more correct, is not always convenient to every practitioner.

Coexisting with diminished hemoglobin we also have at times a diminution of red blood corpuscles, especially in the later cases that are complicated with a true anemia. It is needless to add that in all these cases the blood is deficient in iron. All the chief symptoms are, however, caused by the deficiency in hemoglobin, its resulting interference in gaseous tissue interchange, causing a general derangement in function of the various organs. Fatigue, dyspnea, palpitation, easy perspiration, heart murmurs, arterial and venous murmurs of the jugulars and femorals, all are found in some cases or other of chlorosis, complicating the diagnosis at times so as to cause suspicion of other coexisting maladies, which usually are not present, and if so, not to the extent first suspected.

Concerning latent tuberculosis, there is a popular misconception, even among some ignorant and careless physicians, that in some way these two affections are connected, the one being causative of the other, but this is wrong, and careful study will soon dispel the thought of such relationship.

DIAGNOSIS.

Edema being common in both diseases we must differentiate from nephritis by careful urinalysis. Neurasthenia sometimes comes in for its share of attention, also hysteria, and observing headaches, hemicrania, neuralgia, especially the intercostal and gastric forms, tinnitus, insomnia and other nervous symptoms, warrant us in taking them into account, and often we find one or the other to be the chief affection. Hemorrhages, such as epistaxis, menorrhagia and hematemesis, are misleading, but rare, complications. The respiratory system frequently complicates matters. Slight laryngitis, rhinitis, functional aphonia and dyspnea are observed often. Bronchitis occasionally and tuberculosis develop in a fair number of chlorotics.

This last point deserves elaboration. It is a popular error, I wish to repeat with emphasis, with the public, whose information usually trails fifty years behind professional knowledge, that tuberculosis is caused by chlorosis, or, as they express it, with monthly troubles, especially amenorrhea. This view, I reiterate, is fortified by careless and ill-informed members of the profession, when we know the converse is true; namely, consumptives who have the disease in its incipiency simulate chlorosis, and also have amenorrhea as a simple conservative of Nature's vis medicatrix. We should all strive to correct this false teaching, because the public usually clamor for a restoration of the menses, claiming failure and inability on our part in case we do not accomplish it.

THE LACK OF IRON IN THE CHLOROTIC.

Intestinal and gastrointestinal disturbances are not rare; indeed, Forschheimer's theory is that the intestinal tract is the site and origin of hemoglobin formation, hence chlorosis is caused by alimentary canal disturbances, but this has so far not been proven. Virchow claimed it to be caused by arterial hypoplasia, also not proven, because we find arterial hypoplasia absent in many chlorotics and present in many who are free from the disease. Von Noorden thinks it due to an internal secretion of the ovaries, a disturbance of which causes the defective hematogenesis. Bunge's claim that the cause lies in the adolescent female storing up iron to be used in supplying the livers of her offspring is not easily susceptible of demonstration, though excess of iron is found in the breasts and uteri of adolescents. The fact remains that we are still ignorant of the anatomico-pathologic causes of the origin of this common affection, and a wider knowledge of this as yet unexplored field of blood chemistry may in the future reveal to some investigator what is as yet hidden. As to whether we have less or more of this disease than formerly the best authors differ widely. Vasomotor disturbances are very common among this class of cases, general and localized sweating, flushing, cold areas, as hands and feet, shivering, vague anginal pains, thyroid enlargement and simple polyuria, are frequently noticed, and a pseudo exophthalmic goiter has been noticed by a few. Plausible light on theories of etiology is given by the assumptions of Frederick Taylor, in which he holds that women have less iron, hence less hemoglobin than men, and during adolescence a greater drain is made on them than usual. Healthy women having a reserve store in their liver and spleen can easily supply an excess loss, until Nature comes to their rescue; if not, there will occur a deficit, hence a chlorosis or a chloro-anemia. If to the normal excretory loss we add menorrhagia or other hemorrhages the result is all the more emphasized. But when we have amenorrhea it should be considered a conservative measure, hence protective and beneficial to the patient.

THE TREATMENT BY ADMINISTERING IRON.

Now this view of chlorosis naturally suggests the treatment; namely, to supply what is lacking—iron. Even though there is a want of consensus of opinion as to the etiology, yet all writers agree as to the lack of hemoglobin, and in some cases a deficit in red blood cells, next gastrointestinal disturbances, constipation, bad food, indoor life, unhygienic surroundings, so much so that the treatment mainly consists in bringing about

opposite conditions, to-wit: the administration of iron, regulation of bowels and stomach, purgation, better food, outdoor life, except in the very worst cases where rest at first does most good, and the amelioration of general surroundings. Of all these the administration of iron and purgatives holds first rank, and will probably cure the vast majority of cases.

Now the preparations of iron with which the market is flooded are legion, each one making claims above all others, but few if any come up to the expectation we have from Blaud's mass of the carbonate of iron, either as originally made or compounded with purgatives, also with strychnin, arsenic and sumbul. The number of formulæ in pills or tablets is sufficient to satisfy the most fastidious in almost any case. Special claims have also been made for the lactate and oxalate of iron, also for a number of organic forms, of which ferratin made from the liver of animals is a good example, also numerous solutions such as the peptonates and dialyzed iron, but all of their extravagant claims are not substantiated while many of them are practically inert. In giving iron a pill containing three grains of Blaud's mass may be given after meals, and this amount gradually doubled and even tripled. Even though we know all of this is not absorbed, yet it is best that sufficient be exhibited to supply all deficiency as well as counteract any destructive chemical reactions with the sulphites of the intestinal tract.

When constipated, purgatives, such as aloes, cascara or the salines, alone or in combination with chalybeates, must be pushed to satisfaction to overcome the constipation and its auto-intoxications, and resorption of alimentary toxins. Such hygienic measures as cold sponging on rising, gentle exercise and, those who can afford it, a residence at some iron springs, will add much to a speedy recovery. Relapses must be guarded against and when they occur be treated. An occasional case of pernicious anemia or a latent phthisis may stare us in the face and mock all our therapeutic measures, thus proving the diagnosis wrong. As a rule, however, a careful diagnosis with an iron therapy will conquer the worst cases and make much reputation for the painstaking practitioner. The emancipation from mistaken notions of dress and education, combined with modern ideas of athletics and gymnastics, may do much in preventing this terrible condition among the young girls of the coming generation.

1007 Fifth Street.

DISCUSSION.

DR. E. F. WELLS, Chicago—The investigations of Lloyd Jones show conclusively that every young woman is skirting along the borderline of chlorosis, and that very little is required to cause her to fall over the brink. These investigations have occupied a number of years, and any one who is accustomed to making blood observations as a routine measure in young women will not be long in subscribing heartily to the conclusions of this investigator. That the essence of the matter, from a blood standpoint, is one of failure in the absorption of iron, and not a destruction of erythrocytes nor of too easy loss of hemoglobin from these corpuscles, seems to be almost conclusive when one examines carefully and properly-stained specimens for granules in the nuclei of the white blood corpuscles. In these cells the granulation will be found much less marked than in the ordinarily healthy woman, and showing a remarkable contrast to what is seen in pernicious anemia.

I am myself from the middle west, and I can not subscribe to the opinions put forward by the essayist that one method of diagnosis and one method of procedure which is applicable and useful in New York and Philadelphia, is not applicable to our middle western country. We can examine the blood and the patients just as well in Chicago, just as well on the prairies of Iowa as in New York or elsewhere, and it should be done, and must be done, if we are to make any pretense of doing justice to our patients and to the scientific medicine of to-day.

Any physician may make a careful examination of the blood, count the red corpuscles, estimate the hemoglobin, count the white blood corpuscles, stain them and make a differential count in from one-half to one hour. Such examinations are essential in the diagnosis and in the management of cases of chlorosis. These cases have interested me for many years, and after having read Niemeyer's glowing description of the value of Blaud's mass in the treatment of chlorosis, now incorporated in all the modern text-books, and noting the positive statements made as to the ready and rapid curability of chlorosis, I early followed his plan and met many disappointments. Without any reservation I can affirm, as the result of considerable experience, that chlorosis is not a quickly and easily curable disease. You will hear about others finding it so, but I will venture the assertion that you will not see it in your own practice. No matter what you give, or what you combine with your preparation of iron, you will find, by blood examinations made from week to week, that the patients remain almost at a standstill for some time. After from five to seven weeks, and without any special change in your line of treatment, these cases will improve and do so suddenly and rapidly. I believe that during this apparently stationary condition improvement is going on in certain directions. As is well known, the red blood corpuscles are almost as numerous as in health, but they are small and thin and do not contain the proper quantity of iron. If you will examine the blood of these patients with the hematocrit as well as with the blood counter, you will find that the percentage of blood corpuscles is increasing; that they are increasing in bulk, and judging from subsequent events are probably taking on, gradually, that receptivity for the absorption of iron which they lack and which is essential for improvement. All of these patients should be cautioned against exposure to cold. Cold sponging or bathing in the morning will retard the recovery of these patients. Rest in bed in severe cases is almost a necessity in the beginning of the treatment. After symptomatic recovery these cases still keep along the border of chlorosis, as shown by the tendency to relapses, and it takes years to bring them up to the full hemoglobin standard, and up to the normal standard for the size and number of blood corpuscles of health.

DR. I. A. ABT, Chicago—I wish to emphasize some points in the etiology. First, it should be remembered that chlorosis occurs most commonly about the period of pubescence, indeed, so commonly that one naturally concludes that there is some relation between the development of the organs of generation and the blood condition. A theory on which Dr. Wahrer has dwelt is that of intoxication from the intestinal canal. It has been suggested that girls at the age of puberty are so frequently constipated that a condition of intestinal toxemia is present, but I think greater credence should be given to the first theory. The importance of blood examination has been already emphasized. I believe iron has been given so long in these cases that we almost all look on it as a specific, yet how can the iron possibly act? Is this heavy metal taken up by the corpuscles, or does it act in the intestinal canal in some chemical way so that it combines with toxins or with sulphates, and in this way brings about the elimination of toxic products? This seems to be a reasonable explanation; certainly it appears to me more logical than to believe that heavy metallic iron can do any good by its direct absorption or its appropriation by the red corpuscles. I wish to call attention to the fact that these young people are sick for a long period, and to emphasize the fact that they need careful hygienic management. They should be directed to take a certain amount of rest. Often the pulse is soft and compressible, the heart is dilated, and the seat of blowing murmurs. Patients should be told to take longer hours of sleep or they should be subjected to a partial rest cure. I do not wish to be understood as speaking against iron in these cases, but I have often wondered as to whether it acts in the way we have supposed.

DR. MARGARET T. SHUTT, Springfield, Ill.—I have seen two cases in which most pronounced eye symptoms developed as a

result of chlorosis. One of these cases was seen in New York City. The woman had been sent to hospital with the diagnosis of an intracranial growth, and had suffered for a long time from constant headache and increasing loss of vision. She was unable when first seen to count fingers at a distance of a few inches. The possibility of an intracranial growth was negatived by the history and by absence of focal symptoms, and examination of the blood showed a moderate chlorosis, and this was thought to be a possible cause of the constant headache and the double-choked disc. She improved almost immediately on rest, baths and the administration of iron and bone marrow. Within six weeks vision was almost completely restored, and the headaches disappeared long before this. About one year ago I saw at my home a young girl with a severe choroiditis. Her hemoglobin was reduced to 32 per cent. For a year she had been anemic, and had been treated persistently by her father with many forms of iron and intestinal antiseptics, and by rest, but the anemia seemed to be increasing. I suggested the addition of bone marrow, and whether it was an accidental occurrence or not I can not say, but within a short time she had improved very markedly in every way, and the hemoglobin percentage had increased to 80 per cent.

DR. W. E. DARNALL, Atlantic City, N. J.—So far as I have been able to observe these cases of chlorosis I have been impressed with the importance of the intestinal toxemia theory. Last summer an Irish girl of 22 entered the Atlantic City Hospital during my term of service. The hemoglobin was reduced to 20 per cent. Instead of the usual temperature of 100 or 101 F. her temperature ran between 103 and 104.5 F., which gave strong suspicions of the presence of some other disease. She was, of course, constipated. If she were allowed to go for one day without a movement of the bowel, her temperature, which might have been near normal, would suddenly rise to 104 or over. Repeated examinations of the blood were made to eliminate typhoid fever and malaria, and these were positively excluded. Strict attention was then given to the bowels, and an evacuation was secured regularly twice a day. As soon as this systematic treatment was established the temperature fell to normal, and in a comparatively short time she was completely restored to health, as shown by the blood examination.

DR. WAHRER—I do not think it makes very much difference, therapeutically, what preparation of iron is selected, for no form of iron is absorbed into the system unless it has been converted into the chlorid. Then, why not give the chlorid? Well, it spoils the teeth, produces constipation and blackens the stools, and if long continued, interferes seriously with digestion. While we give peptonate of iron and many other forms, I wish to emphasize the importance of selecting one kind that seems best suited to the individual case. Our success with drugs depends very largely on our special experience with them. I made no special mention of eye symptoms, referring only to the pseudo-exophthalmic cases as an example. There are many cases described as chlorosis which probably should not be classified in this way; nevertheless this term presents a well-recognized symptom complex. I wish to say earnestly, in conclusion, that it is seldom that one finds two people who look precisely alike, and in the same way it is probable that there are no two people who possess exactly the same constitution. I believe every disease or disease complex is modified by this individuality. It is the business of the physician to study this point most carefully and treat the individual who is diseased, as well as the disease. Were this not true, we would need but very few drugs to treat such diseases as are amenable to drug therapeutics. Here again comes in that indefinable but sterling quality every good physician must have to insure success, namely, common sense, or good judgment, or whatever term is best to know it by.

Primary Tumors of the Heart.—Traina has collected in the literature thirty-six primary tumors of the heart. In order of frequency they were myxomata, fibromata, and their combinations, myomata, pure sarcomata, lipomata, fibrosarcomata, angiomata and one chondroma. He describes in the *Clinica Med. Italiana*, xli, 2, a personal observation of a case of primary fibromyxoma.

IS THE ADENOID OPERATION A JUSTIFIABLE SURGICAL PROCEDURE;

AND, IF SO, SHALL IT BE DONE IN ACCORDANCE WITH THE RULES OF GENERAL SURGERY?*

GEORGE L. RICHARDS, M.D.
FALL RIVER, MASS.

At first thought it would seem that to read a paper with this title before this Section is like raising up a man of straw and promptly proceeding to demolish it because it can make no resistance. I hope, however, to demonstrate that a paper with this title is neither untimely nor devoid of interest. The only logical answer to the query is an affirmative one; to which you will all mentally add, "We all operate that way"; and yet some of my observations have made me feel that in a good many instances this operation is not being done as though it were a justifiable surgical procedure, nor in accordance with the rules of general surgery.

Adenoid hypertrophy is a soft growth in the nasopharynx which interferes with nasal respiration and with the proper ventilation of the ear, and experience from the time of Meyer has taught it were better to remove it whenever symptoms of obstruction are present. Because they are easily reached for removal by operation—which operation must invariably be done in the dark—adenoids have frequently been removed in the most incomplete, and in many cases brutal, manner. And since they are done in the worst manner possible in many teaching clinics where Americans who are to be our future surgeons and specialists and members of our societies are taught, I am moved to relate to you some of my personal experiences in witnessing operations of this class done, not ten years ago, but so lately as a few months ago.

For many years German-speaking Europe was the great place for graduate study in the nose, throat and ear, on account of the wealth of material and the fame of the instructors; and of the audience before me probably the greater part have studied in German-speaking countries. As is well known to you all, the German is much more of an adept in the science of medicine and surgery, and especially in the pathology, than he is in the art; and at present most procedures are better done in America than abroad. It was, however, a surprise to me in revisiting a number of clinics to notice with what brutality, or at least so it struck me, the adenoid operation was done. While for obvious reasons I shall not give the names of the clinics or operators, the picture as presented is nevertheless an accurate one, and I have no doubt would be equally true of any number of teaching clinics.

Let me describe to you how I saw the adenoid operation done in five different foreign clinics, all of which have American students. In one the struggling child was taken in the arms of an assistant; the physician sat before the child, with an ordinary laryngeal mirror for a tongue depressor, without a mouth gag; the tongue was depressed, a Beckmann curette introduced behind the pharynx, one or two sweeps made, the child tipped forward and the operation was over. Plenty of blood came, but in the half dozen or more times that I saw the operation done in this way by this operator, and also by other operators in the same clinic, I saw no adenoids of any amount. The finger was not used to determine whether anything was left, nor was any at-

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

tempt made to staunch the blood. The child shrieked loudly, was taken into an adjoining room, and the next child brought forward for operation.

In another clinic in the same city I saw the operation done in substantially the same way, only here the curette was used with such force that in one instance I saw a large portion of what looked like good healthy nasopharyngeal mucous membrane brought out. Here again no after-examination was made to determine whether or not the growth was removed.

In another clinic in another city I saw eighteen children operated on for enlarged tonsils and adenoids in one group. One after another they were seated around the room to shriek, and after they had all been operated on they were brought back for a second examination to see if any portions of adenoids were hanging in the pharynx or bits of tonsils remained. No cocain was used, but in this instance a tongue depressor and a mouth gag were employed, and the operations, while rapidly done, were more scientifically performed than in the two preceding instances.

In a fourth clinic the operation was done without anesthesia and with no attempt at mitigating the pain, yet from the surgical point of view aside from this I have no criticism to offer. Here I saw some twenty children operated on in one seance. While a nurse prepared a child for operation in one chair, the operator operated on another in another part of the room. There was good illumination with artificial light and a forehead mirror, and the instruments used were a most excellent mouth gag, tongue depressor and a Beckmann curette. The tongue was depressed, the curette skilfully used, and in three sweeps, one in the middle and one in each side, the growth was thoroughly removed, and an examination at once made with the finger to be sure that nothing was left. Here adenoids appeared in every instance. In the three preceding clinics I was always surprised at seeing how few adenoids were removed. As fast as the children were operated on they were all sent shrieking and spitting into an adjoining room; and you can imagine the pandemonium present when fifteen or twenty children, shrieking at the top of their lungs and spitting blood, were all assembled in one room. The skill of the operator, however, in this latter case admits of no question, and I am almost tempted to give his name.

In the fifth clinic, which was in England, adenoids were removed in the following manner: Nitrous oxid gas was administered by a skilled anesthetist, a nurse held the child in her lap, another nurse looked after the hands and feet of the patient, while the operator sat before the child, using a forehead mirror and artificial light. Anesthesia was usually complete in less than a minute, the tonsils were removed with the Mackenzie tonsillotome, and the adenoids with the Löwenberg curette followed by the Gottstein. The child's head was thrown forward, the bleeding was inconsiderable, the child was told to spit out the blood, and in about three minutes from the time of beginning the operation the child was able to walk into another room, where it was attended by a nurse until such time as it was able to go home, when it was given printed detailed directions for care for the next few days. For public clinic or hospital work this method seems ideal, since it is accompanied by an insignificant amount of blood as compared with an ether operation, is rapid and painless, and was used in this clinic for all but the very youngest children, whom it was deemed unsafe to anesthetize.

The methods in use in the first four clinics, which were large continental clinics, seemed to me absolutely brutal and incomplete; and I was told by a laryngologist of prominence that the operation itself had fallen somewhat into disrepute, as the growths frequently recurred. As you are all aware the German-speaking authors mostly advise the operation to be done without anesthesia, and now and then some of them claim that it is not painful. Even those who admit that it is painful seem to prefer to operate without anesthesia. Let me quote from several prominent authors: "The operation is painful without narcosis, and when very rapidly done can do harm to a very nervous child." But this author rather deprecates the necessity of employing narcosis, since, he states, the operation can be done in about three seconds. Another writer, an Italian, says: "I do not like narcosis, and only use it when I have children to operate on that can not be held rigidly enough, or when the parents object to its being done without. On the other hand, the pain is of so very short duration, and the operation lasts such a short time, that its risks ought not to be increased by the dangers of using narcosis." Another author states that the children do not realize much of anything until the operation is completed, and that good children have said after the operation that they have not suffered any pain. Furthermore, he states that the tissue contains few or no sensitive nerve fibers, and the child cries because he sees and feels the blood flowing out of the mouth and nose. He says that there are children so unruly, stubborn and obstinate that they can not be operated on except under narcosis. I noticed in my own observations that the children all cried much as they would have done in America; but I am glad to know that they cry, not from pain, but simply on account of the bleeding at the nose and mouth. There are signs of the dawning of a better day for these cases, as in a long monograph of recent date on adenoids, by a continental writer, anesthesia is spoken of as follows: "Local anesthesia is very incomplete and does not spare the child the psychic shock of the instruments and their introduction into the mouth. It is lymphatic, nervous, fearsome, delicate, sensitive children that have adenoids. The forcible holding, the light before the eyes, the large number of instruments, the forcing open of the mouth, the introduction of instruments into the pharynx, which is frequently too small for the instruments, the removal of portions of tissue—is all painful for the patient, as is also the scraping of the growth many times with the curette, which is perhaps not conformable to the pharynx wall, while the child is half suffocated with blood. This procedure frightens the child and causes a nervous shock. On the other hand, the operation is done more easily under anesthesia, and the danger of injury to neighboring structures is less." When I inquired personally among my continental friends as to why they did not use anesthesia for these operations they told me that the anesthesia was dangerous, the operation was short, the pain slight and it was not necessary. A friend of mine, of large private practice in one of the largest continental cities, told me, however, that he invariably used anesthesia, and frequently reoperated after the surgeons who did not regard anesthesia as necessary.

So much for operations across the sea. I am glad to state that, so far as I am aware, most American operators operate under anesthesia, and in a thorough manner. Yet no later than three years ago, in a paper read before this Association (I quote from the published proceedings, 1899), the finger-nail surgery was advocated

as the proper thing for the removal of adenoids, and the writer stated: "I have never seen or rather felt a case of adenoma which was not entirely removable by the finger-nail, provided the latter was in its normal condition and had not been injured or broken. . . . If not all removed, either the same day or the next, if possible, I will again enter the cavity and, if necessary, with the steel finger-nail remove every bit of the diseased tissue discoverable. . . . Two days after, I examine the region, and if everything is well I re-examine after a further period of about three or four days, when, if the healing has been perfect, the upper pharynx will feel smooth and soft, and there will be no danger of recurrence." The steel finger-nail—an instrument much better suited to the dark ages than to twentieth-century surgery—was shown, which was to be used whenever the operator's finger-nail was out of condition. In justice to the members of the Section on Laryngology of 1899, it must be stated that there was general dissent to the reader's proposition. I have also heard of other American surgeons who operate piecemeal for these growths.

The removal of the adenoid growth, if the growth is necessary to be removed at all, is an operation of moment to the person on whom it is done, and therefore should be done in as thorough a manner as possible, and with as little resulting shock. By the rules of general surgery as applied to this operation I mean: general anesthesia in children over two or three years of age, and in all adults in whom it is likely that cocain anesthesia will be insufficient, and proper preparation of operator and instruments, so as to minimize all the risks.

In older children and adults, where the nasopharynx is fully developed, the Schütz adenotome or one of its modifications can be advantageously used under cocain or even without any anesthesia. It is especially adapted for use where the adenoid is mainly central. I have been pleased with it and I know that others also have. I do not think it is adapted for very young children, as in these the pharynx is hardly large enough or sufficiently developed for its successful use. In these, as above stated, I prefer general anesthesia and the ordinary instruments. This adenotome has not yet acquired very general usage. I have never seen it used in any clinic.

The question of the anesthetic to be employed, whether ether, chloroform, bromid of ethyl or chlorid of ethyl, is one that must be determined in accordance with the experience of the individual operator. In most cases I personally prefer ether. Rapid, but careful, deliberate operating should be the rule, the operator being neither in haste to finish in any given number of seconds nor unduly prolonging the operation; and sharp instruments should be used, so that as much as possible the growth may be cut away rather than torn away, so as to leave a smooth cavity. The removal of the adenoids, not of all the structures to the spinal column, is what we desire. The pharynx ought to be covered with mucous membrane and not with fibrous connective tissue which will be a source of dry catarrh during the remainder of the life of its owner.

During the operation I believe in staunching the blood with tampons, since I see no reason for allowing the patient to lose any more blood than is necessary, although I read in all the books that staunching the blood is unnecessary.

Before regarding the operation as finished, determine by examination that the growth has been entirely removed. Keep the child in bed for a day or two following the operation, and do not feel in his nasopharynx at frequent intervals thereafter. If the operation was satisfactorily done no after-examination is necessary.

For the preliminary finger examination previous to operation and for post-operative examinations protect the finger with the rubber finger cot. The details of the operation, preparation, position, asepsis, instruments, etc., do not come within the scope of this paper.

Fortunately, unpleasant sequelæ in the way of sepsis or hemorrhage are almost unknown, considering the number of adenoid operations which are performed. I must, however, considering how difficult it is to properly disinfect or sterilize one's finger nail, protest against its use as a surgical instrument in these cases.

DISCUSSION.

DR. L. C. CLINE, Indianapolis—Two or three years ago I was severely criticised by some of the members of this society because I advocated doing this operation without an anesthetic. I believe the use of anesthetics is overdone in this operation, and only in the exceptional case is an anesthetic necessary. In the majority of cases as good results may be obtained without the use of an anesthetic, and we must admit that there is a danger in the use of anesthetics. Only a short time ago there were 18 or 19 deaths reported from anesthesia, and I am sure anesthesia is not without danger in this operation. We have all learned certain ways of doing operations, and when we become skilled in doing an operation in a certain way, that is the right way for us to do it. Other men may have as good success by some other procedure. My custom is, in the majority of cases, to have the child firmly held by an assistant. I do not have a great array of instruments to show the patient. I do not allow the parents to speak to the child about what I am going to do. I pick up my Gottstein instrument or a modification of it, and before the child realizes what has happened I have done my work. They cry a little afterward, but I would rather they would cry than to have to perform artificial respiration to bring them to after the use of an anesthetic. I have had that experience. We have to adapt our methods to the individual case, I think, and we are not justified in subjecting every case to an anesthetic. I would not use it in my own child, but I would treat it without an anesthetic unless an anesthetic seemed necessary. I believe a good, reliable, efficient operation can be done without even local anesthesia. Such a procedure may be described as brutal and all that, but if the adenoids are soft you can operate without much pain.

DR. J. H. MACDONALD, New York City—This operation is now a great deal in disuse and disrepute by the operators that have done it. The same preparations should be taken for it as for any other operation in surgery. The urine should be examined, the general conditions of the patient should be looked into, and the nervous condition of the patient and the age should be taken into consideration. Many of our clinics do not examine the urine, and do not even know whether the bowels are loaded, as happened in a case related by Dr. Cline. All these things are overlooked in what is considered the little operation for the removal of adenoids. This operation should be done with the proper technic, with the aid of nurses and intelligent assistants. There should be no struggling. Then the use of anesthesia would not be in disrepute. In regard to the choice of an anesthetic, I have, with Dr. Gleitzmann of New York, used bromid of ethyl in over 500 cases without a death. I have used the A. C. E. mixture and also chloroform. We are careful in the selection and the use of an anesthetic. We take the condition of the blood into consideration. We see that the child is thoroughly relaxed, that is, of course, in children over two years of age and who are not of a nervous temperament. That has been the teaching of Dr. Gleitzmann while I have been his assistant for over five years. In regard to ether, there is an unknown quantity. But if we go into the subject with the same care as if we were to do a laparotomy, there would not be half the deaths.

DR. SARGENT F. SNOW, Syracuse, N. Y.—I agree with Dr. Richards that this operation should be done as a surgical pro-

cedure. For about three years I have been trying the use of bromid of ethyl. I have also used other anesthetics, such as ether and chloroform and laughing gas. I must say that if I can have an assistant to hold the patient, who is familiar with the work and an anesthetist who is familiar with giving bromid of ethyl, I prefer it to all other anesthetics. With bromid of ethyl we get anesthesia in from 90 to 120 seconds, and sometimes in 60 seconds sufficient to amputate both tonsils and remove the adenoids. Almost immediately afterward our patient is conscious, with no sickness and with very little hemorrhage. This anesthetic is most excellent if the drug be fresh and our assistants acquainted with their work. The laughing gas in my hands so far has not proved all I wanted. The anesthesia I get from it is not sufficient. Perhaps my anesthetist has not pushed it far enough, but we do not get sufficient relaxation. I do like the patient in an upright position, which seems safe when we use bromid of ethyl.

Dr. G. McAuliffe, New York City—I did not understand from Dr. Richards' paper whether or not he staunched the bleeding. As soon as the adenoid tissue is all out, I have not witnessed any bleeding.

Dr. Richards—I did not give the details of the operation, but my plea was for good surgery. The current number of the *International Journal of Surgery* contains an article in which my own views are stated.

THE DIAGNOSIS OF CARCINOMA OF THE LARYNX.*

OTTO T. FREER, M.D.
CHICAGO.

It is unfortunately true that ordinarily carcinoma of the larynx is not discovered until nothing but total laryngectomy offers the patient a chance for existence. One of the reasons for this is the fact that the diagnosis of the affection is often difficult and may be impossible for even an expert. Another cause for the lateness of recognition of the disease is the slight regard usually paid by the patients to the persistent hoarseness that may precede the graver manifestations for years as the only symptom. A third and avoidable reason for the unrecognized advance of malignant laryngeal tumors is the widespread indifference to the acquirement of even moderate skill in laryngoscopy shown by a great part of the profession. Many physicians treat patients with chronic hoarseness by general means and do not even inspect the larynx. I have known a patient to be sprayed for six months for supposed laryngeal catarrh by means of an atomizer and tongue depressor while his unseen carcinoma rapidly advanced to a hopeless stage. In another instance the laryngoscope was not used until the carcinoma had penetrated the laryngeal cartilages and appeared as a tumor in the neck. A glance at the literature of laryngectomy will show how late carcinoma of the larynx usually comes to the operator. Chronic hoarseness, especially in men past forty should make a laryngoscopic examination an imperative duty to all practitioners.

There are no general conditions with the exception of age and sex that are of use in determining the existence of carcinoma. Until the disease has advanced to the stage of dysphagia, extensive ulceration, sloughing and perichrondritis, it does not interfere materially with health.

Though most of the patients affected with the disease have passed their fortieth year, a large proportion of cases is seen before this period and even childhood is not exempt. This is shown by the statistics of Sendziak containing 479 cases of carcinoma of the larynx and that of E. Kraus with 187 cases, a total of 666. Five of these were found in the two first decades of life, 26 between the 20th and 30th year, 59 between the 30th and 40th, 170 between the 40th and 50th, 264 between the ages of 50 and 60, 110 between 60 and 70, 15 between 70 and 80.

Sex is of importance in determining the existence of laryngeal carcinoma, as the statistics of numerous observers show that men are from six to seven times more liable to the disease than women.

None of the symptoms of carcinoma are of much value in proving its presence, but they are of great use in arousing suspicion of its existence. In the majority of cases hoarseness is the sole evidence of commencing malignant disease for a long period, generally from one to three years. Chiari mentions a case in which hoarseness lasted nine years before other symptoms made their appearance and voice disturbance in his other cases extended over an average of two years before there was a change in the manifestations. This long period of comparative latency of the disease gives abundant opportunity for conservative operative interference and serves to differentiate carcinoma from the rapidly destructive laryngeal lesions of syphilis and tuberculosis.

The symptom of pain appears in the later stages of carcinoma, characterized by sloughing and ulceration. It is common to all the ulcerative affections of the upper larynx and therefore not peculiar to malignant disease though in some cases a prominent feature. It serves to exclude the benignant growths from consideration as these are never associated with pain. In carcinoma this generally takes the form of otalgia, occurs during swallowing or sometimes spontaneously and darts from the larynx to the ear, angle of the jaw or back of the head. Fraenkel states that it always appears in the ear corresponding to the side of the larynx affected, and that he has never found pain as a symptom of carcinoma where the epiglottis or aryteno-epiglottic folds were not ulcerated. Ulceration of the cords did not, in his experience, give rise to otalgia. Delavan regards lancinating pain as an important symptom, but his views are not shared by the majority of authors, who agree that it is usually a late and inconstant manifestation. Scheier found in 102 cases of carcinoma only 9 who complained of otalgia or pain radiating to the back of the head. In my experience pain is not a regular or prominent feature of laryngeal carcinoma.

The dyspnea of carcinoma ordinarily lasts many weeks or months before it becomes dangerous, but if perichondritis or other acute inflammatory complication occur it may come on suddenly, and whether its onset be fast or slow it almost invariably demands tracheotomy. A history of slowly increasing laryngeal stenosis in an old man is very suggestive of carcinoma. The stench that carcinoma gives to the breath is a characteristic but very late symptom, which may also occur in syphilitic necrosis of the cartilages.

It is thus evident that the patient's general state and symptoms offer but slight aid in making a diagnosis and that dependence must rather be placed on laryngoscopic and microscopic examination.

It is customary to divide carcinomata of the larynx into intrinsic ones; those originating on the vocal cords, ventricular bands, in the ventricle or inter-arytenoid or subglottic regions and extrinsic carcinomata; those seated on the epiglottis, aryteno-epiglottic folds, in the fossa pyriformis and on the posterior surface of the cricoid ring. Observers agree that carcinoma has its origin

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. J. F. Barnhill, C. R. Holmes and G. H. Makuen.

on the vocal cords much more often than elsewhere in the larynx. Moritz Schmidt says that the center of the membranous part of the cord, so often the seat of benign growths, is very seldom attacked by carcinoma, and states that carcinoma is never primary over the processus vocalis according to his experience and that of B. Fraenkel and others. The inter-arytenoid region, the favorite location of tubercular papillomatous granulations, is rarely the source of carcinoma, while next to the vocal cords the ventricular bands are its favorite seat.

Intrinsic carcinomata are commoner than extrinsic ones, the epiglottis being more frequently attacked by the latter than other parts, though Jurasez finds carcinoma of the posterior surface of the cricoid cartilage not rare. The fact that the vocal cords are the favorite seat of carcinoma would be of more diagnostic value were it not that they are a common point of attack for so many other morbid laryngeal conditions. Most of the benignant growths begin here and tuberculosis and syphilis are common in this location.

Carcinoma in its early stage may have a deep or superficial origin, growing in the submucous tissues or invading the structure of the mucosa itself. It often

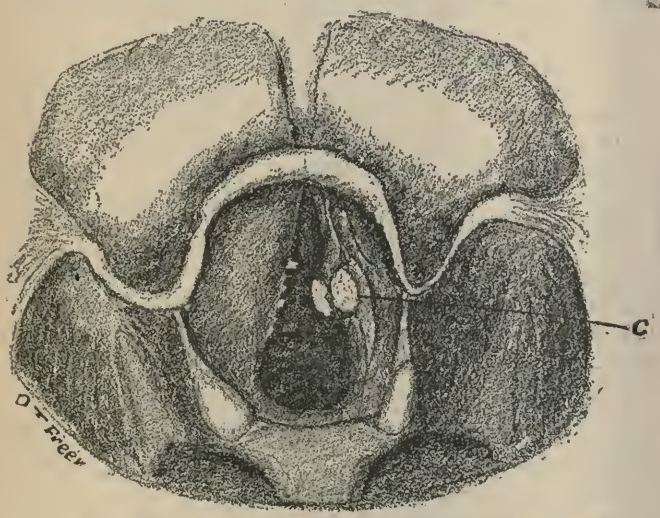

Fig. 4.—Polypoid carcinoma of the larynx. *c*, Carcinoma.

looks like papilloma and this resemblance may be due to the carcinoma tissue itself, when this is superficial and has the form of a hard verrucous, generally white rough thickening, the so-called pachydermia verrucosa. In other cases the carcinoma is of deeper variety and invading the submucous depths is covered with a growth of softer true papillomata which may precede its appearance for years, be removed again and again until finally the malignant tumor reaches the surface, appearing as a whitish yellow mass. In other cases the neoplasm is a mixture of true carcinoma elements surrounded by a zone of simple papillomata. In Figure 4 a number of accumulated papillary prominences may be seen fringing the edge of the right cord heralding the advance of the carcinoma across the anterior commissure and into the substance of the right cord. Moritz Schmidt has found that carcinomas that announce their coming to the surface by a growth of simple papillomata are apt to originate deeply near the perichondrium and to cause perichondritis early. The aspect of the surface of early carcinoma may strongly resemble that of papilloma; in fact, be of a truly papillomatous nature and so leave the most experienced observers in doubt. A piece removed for histologic examination may add to the confusion if too superficially removed. This is well shown in one of Chiari's cases. The patient had pieces excised for microscopic diagnosis five times during four years, the last piece only showing true carcinoma, the others being pronounced merely suspicious papillomata.

It is to the base of the neoplasm rather than to its surface that attention must be directed in the diagnosis of carcinoma from simple papilloma or other benign growths. Though there are even some pedunculated early carcinomata the base of the papillary carcinoma is generally broad, the mass of the growth seems to form a part of the larynx invaded, substitutes normal tissue by its elements and therefore rises but little above the surface while the superficial nature of the attachment of papilloma is striking. It is usually multiple while commencing carcinoma is solitary. The mosslike grouping of the long slender papillæ of papilloma forms a delicately regular structure in marked contrast to the broad, short and irregular proliferations of carcinoma. A typical papilloma is shown in Figure 8. I have removed successive crops of papillomata from the larynx of the patient from whom I made this drawing. The first operation was in 1897. The recurrences have all been typical papilloma.

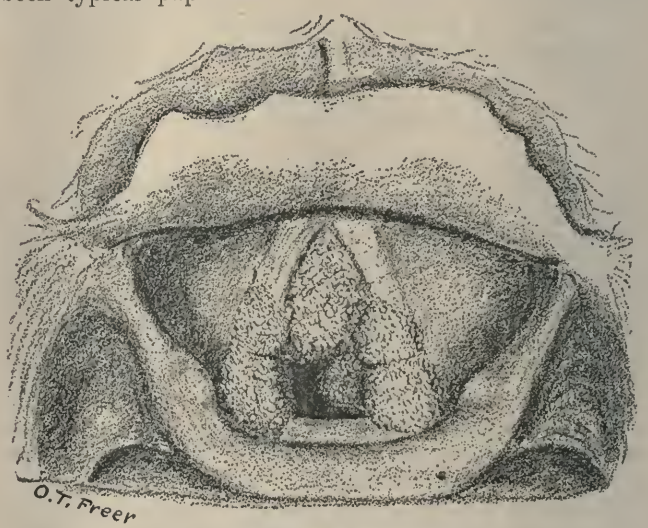

Fig. 8.—Papillomata of the larynx.

Virchow states: "If the papillary or aborescent outgrowth be seated on a narrow, superficial, non-suspicious base the neoplasm may be regarded as non-malignant. The base of the tumor constitutes the difference between the wart and the papillary carcinoma." Chiari says that the base of the papillary excrescences of carcinoma bleeds much more severely when these are cut away than does the base of a papilloma. The surface from which a papilloma arises is not altered or inflamed, while in the course of time an inflammatory area usually appears about the cancerous excrescence according to the rapidity of growth and consequent irritation of the tissues invaded. This is associated with edema of the mucosa due to the occlusion of vessels and venous stasis caused by the advancing growth. Ordinarily it is no hard matter to distinguish simple papilloma from carcinoma.

The form of tumor called carcinoma polypoides by Fraenkel is regarded by him and Semon as even more common than the papillomatous variety, but is less liable to be mistaken in diagnosis. It appears most commonly as a tumor of the cord in the form of a flat broad elevation. Benign growths grow in height and breadth, carcinoma more in depth, replacing normal tissue, so that carcinoma polypoides invades the glottis but little while it enters deeply into the cord. The surface of this form

of tumor is smooth at first or slightly irregular, its color grayish-white or even whiter than the cord itself. This condition is shown in Figure 4, where the button-like white epithelial nodules of the carcinoma are seen inlaid in the mucous membrane which is thrown into irregular folds by the carcinoma tissue underneath, while the outlines of the cord, ventricular band and ventricle are already effaced. The patient from whom I made this drawing was first seen by me, together with Dr. George Torrison, in October, 1901. His only complaint was of hoarseness of a year's standing. A series of illnesses prevented his seeing us again until January, 1902. The progress of the carcinoma in the interval is shown in Figure 5. We each removed a piece at this time for microscopic examination and typical carcinoma was found. The larynx was removed by the late Dr. Christian Fenger and it was discovered that the tumor, while showing such apparently small endolaryngeal progress, had already perforated the thyroid cartilage anteriorly. Figure 6 shows how the growth looked when the larynx was opened anteriorly and emphasizes how much more extensive carcinomata usually are than surface appear-

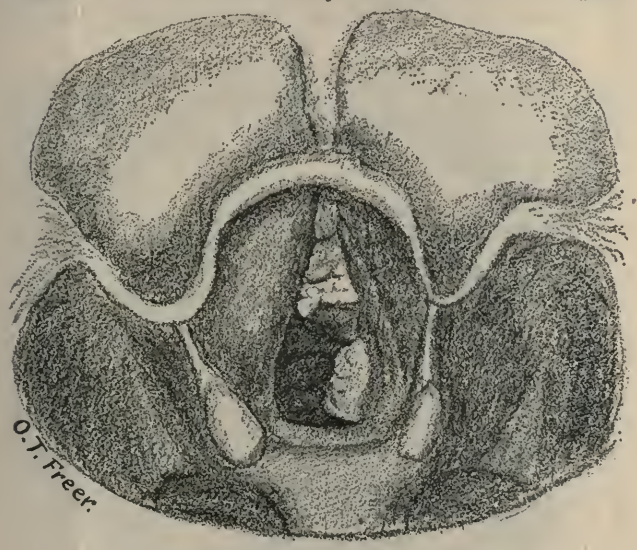

Fig. 5.—The same carcinoma as Fig. 4, three months later.

ances warrant. The left vocal cord in this case when first seen was not quite as movable as was the right, but even up to the time of operation retained a good deal of motion as the neoplasm had spared the arytenoid region and merely destroyed the membranous part of the cord.

The form of laryngeal carcinoma called carcinoma diffusum by B. Fraenkel appears most commonly on the cord and as a diffuse, superficial infiltration, which is distinguished with difficulty from other thickenings of the mucosa and is most likely to be mistaken for syphilitic or tubercular infiltration, pachyderma of the cords or hypertrophic forms of chronic laryngitis. The diffuse swelling enters into the healthy tissues without sharp border and though at first it resembles a mere thickening of the mucosa in time it becomes nodular and the color of the thickening variegated. Some places where the carcinoma tissue is superficial, are whitish, others hyperemic. The general outline of the cord and often its mobility are maintained. A diffuse carcinoma of the epiglottis and aryteno-epiglottic fold is shown in Figure 1. Its form is smooth and nodular while it merges insensibly into the surrounding tissues. Dr. E. T. Dickerman kindly allowed me to make a drawing of this larynx which was removed from a patient in his practice by Dr. A. D. Bevan, a perfect recovery following the operation.

Carcinoma of the ventricular band or aryteno-epiglottic fold is more vascular than that of the cord and contains less of epithelial elements, in accordance with its origin from mucosa covered with cylindrical epithelium. The color of the growth therefore is usually pink or deep red. Growth is also more rapid than on the cords and exuberant cauliflower excrescences commoner.

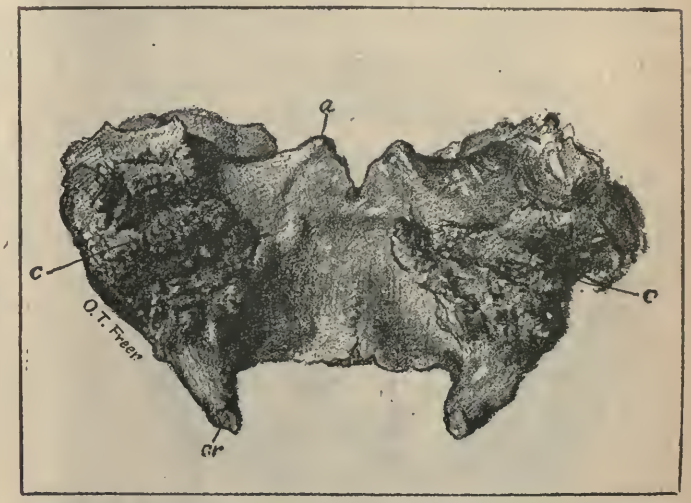

Fig. 6.—Carcinoma of Fig. 4, the larynx opened anteriorly after laryngectomy. *cc*, Bisected carcinoma. *cr*, Ring of cricoid cartilage severed. *a*, Arytenoid.

Very difficult to recognize in the earlier stages is carcinoma of the ventricle of Morgagni, or carcinoma ventriculare. This type of tumor for a long period remains hidden and pushes the cord, ventricular band and aryteno-epiglottic fold before it, interfering with the motions of the cord and finally forcing it into a posi-

Fig. 1.—Diffuse carcinoma of aryteno-epiglottic fold and epiglottis.

tion of extreme adduction, so that it crosses the median line. The mucous covering of the bulging swelling is hyperemic, but intact for a long time. In the early stages carcinoma ventriculare is hard to differentiate from swellings of the ventricular band or aryteno-epiglottic fold. Deep-seated gummata, perichondritis interna of the thyroid or cricoid cartilage, benign growths of the ventricle, distention of the occluded ventricle may present similar appearances, so that diagnosis by inspection and microscopic diagnosis may both be im-

possible, as instruments can not readily get at the hidden growth to remove a piece.

When carcinoma occupies the posterior surface of the cricoid cartilage it presents great obstacles to diagnosis. All that may be visible is hyperemic swelling of the mucous membrane of the arytenoid region at its posterior part, with more or less interference with the motion of the arytenoid bodies. By the time that the carcinoma has advanced far enough upward on the back of the larynx to become visible it usually has attained extensive growth, so that perichondritis of the arytenoid

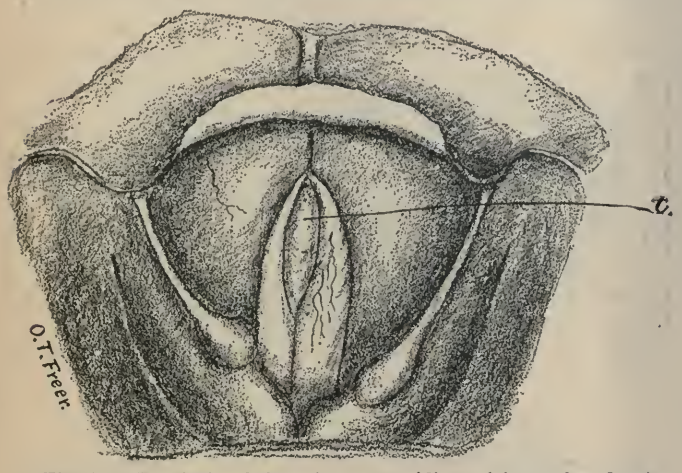

Fig. 10.—Paralysis of the crico-arytenoidi postici muscles, due to subglottic malignant tumor. *t*, Portion of malignant tumor pushing up between adducted cords.

cartilages is not uncommon as a complication. The chief symptom is dysphagia.

Carcinoma of the epiglottis usually occurs as a hard circumscribed tumor of a papillary or cauliflower form with constricted base, but is also found as a diffuse carcinomatous infiltration, as shown in Fig. 1. It may ulcerate early, so that destruction exceeds new growth, or form tumors so large that they prevent swallowing. The most marked symptom is dysphagia, and when the motions of the thickened epiglottis are stiffened or lost, food is apt to enter the larynx.

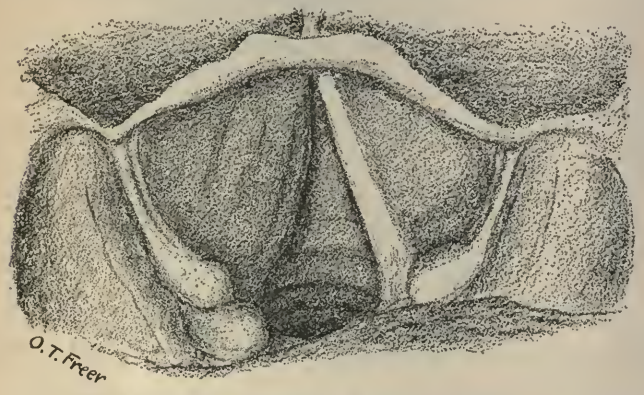

Fig. 15.—Syphilitic infiltration of right cord and ventricular band with fixation of cord.

A symptom of some importance in the early diagnosis of carcinoma of the larynx is retarded or lost motion of the cord. Semon regards this sign as of great value, but as there are other conditions beside carcinoma that quite often create it, it should not be overestimated. Schmidt says that the symptom will occur early if the tumor or its inflammatory surroundings have penetrated beyond the tissues of the cord fixing it to the neighboring parts but as long as it is confined to the cord loss of motion will not occur.

The motions of the cord are most seriously and often impaired by tumors that interfere with the movements of the crico-arytenoid joint, either by destroying the joint or by rendering it immobile by thickening the tissues about it, but neoplasms that have entered the muscles of the cord and transformed it into a rigid mass will also limit or stop its movements. When carcinoma is hidden in the subglottic space its first symptom may thus be fixation of the cord while the tumor may not be laryngoscopically visible.

Loss of motion of the cord in carcinoma is not only due to direct interference with its structure or the crico-arytenoid joint, but may be due to paralysis of the crico-arytenoideus posticus muscle. This is described by Moritz Schmidt as the result of a carcinoma in the sinus pyriformis, while Semon has seen double posticus paralysis with median fixation of the cords on account of the growth of a subglottic tumor. Figure 10 shows median fixation of the cords which seemed to me due to posticus paralysis caused by a large subglottic malignant tumor. The case was seen by me two years ago. The neoplasm when I made the drawing had penetrated the tissues outside of the larynx and trachea so

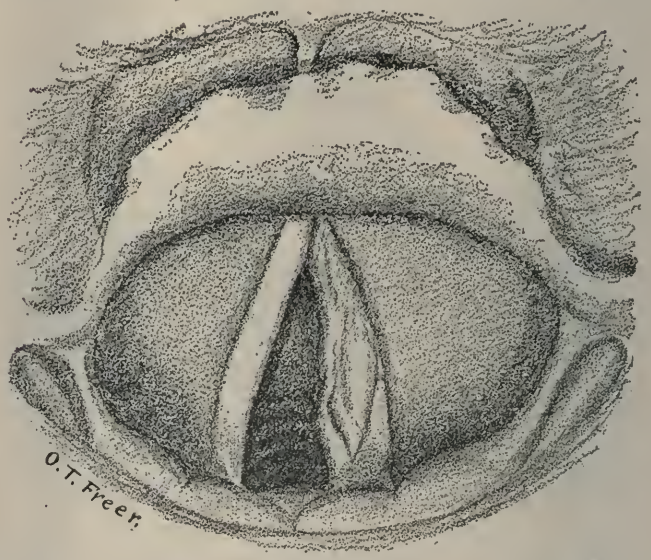

Fig. 11.—Tubercular ulceration of left cord with immobility.

that it caused pressure on the recurrent laryngeal nerves sufficient to destroy the function of the nerve fibers supplying the abductor muscles, a portion of the nerve which Semon has shown to be more vulnerable than the adductor part. A small portion of the growth may be seen forcing its way upward between the cords.

Both syphilitic and tubercular infiltrations may give rise to Semon's loss of motion of the cord as well as carcinoma. This is shown by two cases of my own. The first, Figure 15, had been considered carcinomatous infiltration by another physician, largely because of the fixation of the right cord accompanying a diffuse swelling of the cord and ventricular band. A suspicious white patch on the posterior pharyngeal wall on the summit of the infiltrated prominence shown in the drawing led me to a diagnosis of syphilis. Iodid of potassium produced complete recovery.

Figure 11 represents the larynx of a man, aged 63, who presented himself with complete immobility of the thickened left vocal cord with a shallow ulcer extending along its free border. Considering the patient's age and sex, carcinoma, possibly hidden in the subglottic space, was suspected. Examination of the lungs showed both

apices free from disease, but subcrepitant râles at the lower angle of the right scapula and the presence of numerous tubercle bacilli in the scanty sputum with the absence of anything like tumor formation as base for the ulcer convinced me that the disease was a tubercular infiltration of the cord.

Early carcinoma of the larynx is seldom hard to distinguish from tubercular infiltration, which is usually so characteristic that the laryngoscopist recognizes it at a glance. The typical pale, edematous, symmetrically swollen epiglottis and aryteno-epiglottic folds shown in Figure 13 can be nothing but tuberculous. In addition coexisting lung tuberculosis almost invariably makes the diagnosis easy. The usual symmetry of the lesions and pallor of the mucosa are characteristics of tuberculosis as opposed to the unilateral start and irregular, tumor-like growth of carcinoma, together with the deeper color of its surroundings and usual good health of the patient. The enormous frequency of laryngeal tuberculosis, however, often brings odd forms to view that have deceived the most experienced. Chiari pronounced tubercular a granulating ulcer which later proved to be carcinoma. Moritz Schmidt reports the

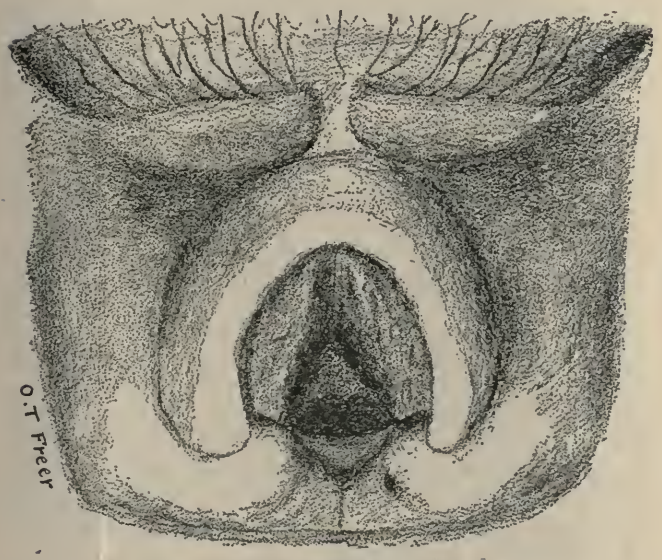

Fig. 13.—Tubercular infiltration of the larynx.

same experience. He mentions a case which Semon declared syphilis, Schmidt's assistant carcinoma, Fraenkel inflammatory infiltration, while Weigert's final microscopic diagnosis was tuberculosis. A tubercular infiltration of one cord may at times resemble carcinoma diffusum, papillary excrescences on ulcers with infiltrated base may simulate papillary carcinoma. This condition is common in the inter-arytenoid region, but here carcinoma very rarely has its beginning.

(To be continued.)

Honors for Brouardel.—On the occasion of the conferring of the title of "grand officer" of the order of the Legion of Honor upon Brouardel, his friends presented him with a souvenir medallion at a public ceremony, January 18. His achievements in forensic medicine, in hygiene and as dean of the medical faculty were reviewed by pupils of his who have also gained renown in these lines. The various medical and other societies of which he is or has been president were also represented among the speakers, as well as various departments of the government. The latter expressed the national gratitude for Brouardel's leadership in the present campaign against tuberculosis, to which he is now devoting almost all his energies.

UNIFORMITY IN MEDICAL PRACTICE ACTS.*

N. R. COLEMAN, M.D.
President of the Ohio State Board of Medical Registration and Examination.
COLUMBUS, OHIO.

It is but a brief period since a majority of the states enacted laws controlling and directing the practice of medicine, and yet this time has witnessed many and far-reaching changes. Some can recall when a person could, without special preparation or education, announce himself a physician and prey on the community without molestation; when medical colleges could graduate their classes after two courses of lectures of twelve weeks each; when a charter, irrespective of faculty, equipment or the fitness of its students, constituted a college; when the errant quack and vampire rode over the land in palace cars, robbing the people without let or hindrance; when the self-constituted midwife infected the mother or mutilated the child, and there was none to stay her course of death and destruction. But thanks to the labor, energy and wisdom of medical men the darkness and melancholy of those days have passed, and the brightness and hopefulness engendered by education, skill and law, are about our path to-day. There are now but few and isolated areas in our country over which the potent arm of the law does not extend protection by defining who shall guard the lives and health of its inhabitants. It is true that many of the states and territories have crude and imperfect laws, yet these are far better than no laws at all, and serve as foundations upon which the more earnest and enlightened members of the profession can base their efforts to dignify and elevate their calling and protect the people from fraud and imposition.

The laws that have been enacted do not seek to deprive people of their choice in the selection of a physician, or of their preference for any school of medicine whatsoever, but they do reserve the right, and wisely so, to determine the fitness of the physician in regard to educational qualifications and moral character. Their aim is to furnish, in higher degree, intelligence and medical skill exerted for the saving of human life and for the relief of suffering. One is often aroused to varying degrees of amazement, disgust, indignation or pity at the selfishness and greed which seek to weaken and overthrow such beneficent provisions. The legislative lobbies are thronged, not only by the unqualified, the dissolute, blatant quacks and the exploiters of new and strange arts of healing—all seeking the destruction of medical laws, but in some instances these have been joined by students in medical colleges seeking exemption from state examinations. No college claiming the facilities necessary for imparting an efficient medical education can tolerate such action by its students, and the students themselves are blind to their future interest and ignorant of the history of the medical profession when guilty of so gross an error.

Examinations are not burdens peculiar to physicians. All professions and callings, governmental and municipal departments, require recorded proof of the qualifications possessed by those seeking positions of trust. The moral support in the community educated to the need of these and similar requirements, will, ere long, enable the supporters of medical legislation to utilize some of the energies required to maintain our present position, in extending and perfecting our system of laws. To these laws must be given the credit of accom-

* Presidential address before the National Confederation of State Medical Examining and Licensing Boards, Saratoga Springs, N. Y., June 9, 1902.

plishing the rapid and much desired reforms in medical education which have been indicated, and their abrogation would result in a lapse into much of the old-time disorder and neglect from which we have but just arisen.

The most urgent need, just now, it seems to the writer, is that a united and even front should be presented to the enemies of an enlightened and well-qualified profession. There is the old simile of the chain—not stronger than its weakest link. To attain our result we do not have to weaken the stronger links, but certainly we must strengthen the weaker ones. One state should not become the dumping-ground of another's refuse. We must get together; become embued with the same high ideals; extend the helping hand, and then hold on. It is urged by some that it is not necessary that the same high degree of efficiency in the education of physicians be extended to all parts of this country; that those who practice in the more sparsely settled and less cultured sections do not require so thorough an education as those located in cities and older communities. The fallacy of such argument lies in the assumption of unequal valuations of a life under mere circumstances of location, for experience has demonstrated that remoteness from counsel, skilled nursing and improved armamentarium and supplies requires a higher degree of natural and acquired ability to cope with accident and disease than when such aids are available. The average severity of illness and accident is too uniform to invalidate the above conclusion. The inference, then, is that it is essential that the various medical practice acts of the states and territories should be uniform in character and administration, for the greatest good to accrue to the greatest number. If this be so, let us briefly consider the important points of the various laws in which there seems the greatest discrepancy in application; for to this organization is given the opportunity of exerting the most direct influence toward uniformity in the scope and administration of medical legislation throughout the United States.

NECESSITY FOR A MORE UNIFORM DEFINITION OF THE PRACTICE OF MEDICINE.

This is the first point to which I would call your attention. There is no one subject connected with medical practice acts which has given rise to so much controversy and contention in the courts, causing increased expense and annoyance to those charged with the administration of the laws, as a definition of the practice of medicine; and with reason, as most of the violations of these laws and the prosecutions which follow involve this very question. This definition in every law, with, to the best of my knowledge, scarce an exception, has sometime proved defective when tested in the courts, and has demanded amendment; and to-day few of these definitions are adequate to successfully meet all the methods devised for their evasion. With due consideration of the accumulation of legal opinions given during the past fifteen years by the various courts throughout the country, and of the extensive and varied experiences of the state boards, it would seem that now a definition might be framed in terms sufficiently broad and explicit to include all possible violations of this provision. The need of such a definition is too obvious to require discussion. Therefore, your presiding officer would suggest the appointment of a committee composed of one member from each state, district and territorial board of medical licensure, to frame a definition of practice of medicine; and that such committee report the result of its labors at the next annual meeting of this body. Such a report would embody the full amount of our knowledge on this most important subject, and will be of permanent value as a standard by which old laws may be bettered and new ones framed, thereby leading, in time, to the greater uniformity and efficiency of all medical practice acts.

MINIMUM STANDARDS FOR ADMISSION TO MEDICAL COLLEGES.

During the period just preceding the more general enactment of medical practice acts there were admitted to medical colleges the greatest number of students devoid of the necessary preliminary education ever known in our medical history. A spirit of commercialism was then rampant among many of the medical colleges, and has been one of the greatest curses with which the medical profession has had to contend. In fact, it was a leading factor in establishing medical legislation, as the earliest efforts in that direction all empowered the boards to determine the standing of colleges. From a careful examination of state laws and of information sent out during the past few years by the medical colleges, one may believe that there is a rapid and substantial advance in the requirements for admission to medical courses; and this has seemed more notable and uniform since the minimum standard for entrance to medical colleges was adopted by this organization in 1899. This standard has been enacted into law, in its entirety or in part, by a few of the states and has been conformed to by some of our colleges. It is sufficient for immediate demands, but in a few years it should be made more stringent. In the meantime there is plenty of work to be done in securing greater conformity to its provisions. A number of states require only a common school education; others have requirements so vague or ambiguous that their exact determination is difficult. Such conditions are not to the best interests of either the public or the medical profession. Besides being a source of confusion and perplexity, they tend to foster commercialism among such institutions as can legally admit students upon a low standard of qualifications. As stated before, we may not be ready for the general adoption of the highest and best standard, but such as we have—and it is far from an insignificant one—let us uphold and extend till the country is a unit in demanding at least so much as a minimum requirement.

CURRICULUM AND TIME OF STUDY.

A subject which is exciting great interest and much discussion concerns the curriculum in colleges and the time of study, for recent requirements have greatly complicated what was once a very simple question.

Some years ago, when the requirements were three years of study with two courses of lectures, the instruction consisted of lectures on the fundamental branches repeated year after year, and the time requirement was met by study under a preceptor. Under such regimen a student could pursue but a small part of the course of study now required, yet these men, with a few facts well learned, have generally discharged their professional duties in an acceptable manner and have prospered in their business. Thirty years ago colleges were not very numerous and were well attended. This gave rise to a belief that it was a lucrative business to conduct a medical college. A charter was easily obtained, and so-called medical colleges sprang up all over the country in astonishing numbers. Requirements existed as much in the breach as in the observance, the only one uniformly exacted being that dues should be paid. These conditions did not obtain in all our colleges, but in far too many for the public good or the honor of the profession.

With this brief review of the courses existing in the past we turn to those which obtain in the present. In examining the various catalogues issued by medical colleges one is astonished to find the wide variations in preliminary requirements and in courses and time of study. Special influences, as the age, location and resources of the institution, modify in marked degree both requirements and curriculum. The time of study now required by most colleges is four years, during each year of which time the student must attend a full course of instruction extending over a period of at least six months. With such a statement laid down let us see how it may, and possibly often does, operate. The student enters the medical college wholly ignorant of medical technicalities, and, from this obstacle, for the first six months his progress in medical subjects is almost nothing. At the end of the term he engages in some other vocation till the opening of another year, and so he may be employed during each interim. At the end of the four courses his diploma is granted upon what is in reality but little over eighteen months of real study of medicine, instead of the four years which is presumed. State medical examining boards should make a clear and specific definition of what is meant by four full years of study and by four full courses of lectures each in four separate years, and then exact it from all who apply for examination.

Would it not be more definite for state boards to require students to be absolutely engaged in the study of medicine for a period of nine months in each of four separate years, and that during each of these periods at least six months must be spent in a reputable college, designating the number of hours to be spent in laboratory and class-room. Such specific statements could not admit of doubt or misconstruction.

ADVANCED STANDING.

The allowing of advanced standing to graduates in arts or science, in dentistry, pharmacy or veterinary medicine, is a subject to which much thought has been devoted and concerning which many suggestions have been evolved, but all seemingly without reaching a satisfactory conclusion.

It has been one of the chief aims of state boards to promote and encourage, in all honorable ways, the most complete educational training before entering upon the study of medicine. For this reason they have allowed the college to at once advance a student with a degree in arts or science to the second year's course, provided the student has made a satisfactory examination on the first year's curriculum. Such students have been well trained to mental efforts and habits of study which should enhance their progress in the study of medicine; on the other hand, the courses in anatomy, materia medica and physiological chemistry are not usually given in literary institutions with that exhaustiveness of detail demanded in the technical school. In the opinion of many, of whom I am one, these factors quite fairly offset each other, and that it is equable and just to allow advanced standing to graduates of literary colleges which require four collegiate years of nine months each and which include in their curriculum the branches taught in the first year's work of a first-class medical college. In the case of graduates in dentistry, pharmacy and veterinary medicine advanced standing should be withheld, unless their literary training is equivalent to that leading to an A.B. or B.S. in course, and their work has included that of the first year in a first-class medical college; because the mental training of their technical instructions alone would not warrant such advanced standing.

It is to be deeply regretted that some states still admit undergraduates to examination and so to the practice of medicine; and it is sincerely hoped that they may soon find opportunity to abandon this practice.

NIGHT SCHOOLS AND SUMMER SCHOOLS OF MEDICINE.

Another disturbing factor appears in the summer schools and night schools of medicine. These, with scarce an exception, have been inadequately equipped to acceptably discharge their duties as educational institutions. The only excuse for their existence being to serve as makeshifts, by which those unable to devote themselves to the requisite time, attention and study demanded by the regular course, might worm their way into the medical profession. Such institutions should not be recognized by state medical boards. A most serious objection to their recognition is the limitation of work and of opportunity imposed by the hours utilized. The extensive curriculum now demanded in good colleges requires for its fulfillment ten or twelve hours of absolute labor each day during four yearly sessions of from six to nine months each. Moreover, part of the work can not be so successfully prosecuted by artificial light. One of the most essential features of a medical education is a thorough clinical training, and this is almost wholly impracticable, as cases for instruction can not be utilized at night without entailing detriment and unnecessary hardships upon patients; and few hospitals would tolerate such disquieting and unseasonable intrusion. If the student has been employed for eight or ten hours in some other vocation, he requires rest and is in no physical condition to spend half the night listening to lectures, working in laboratory or dissecting room. Such an attempt must lead to either a neglect of business, failure in studies or physical disaster. Summer schools labor under the disadvantages of high temperature, the absence of many skilled instructors from the cities, the falling off of clinical material, the difficulty in prosecuting thorough anatomical work, etc. I may say, in passing, that the Ohio State Board has never recognized the work done in any night school, and in but one instance has it admitted that of a summer school.

The objects of medical legislation include the fullest protection to life and the amelioration of suffering. To boards are given the execution of certain provisions, but they should also ever strive to act in accordance with the purposes and intent of the law. To recognize schools lacking in the essential facilities for efficient instruction in medicine would surely violate the spirit which prompted the enactment. With splendid colleges all over this country, possessing the best equipment and strong teaching faculties, offering thorough medical training at but nominal expense, there is no necessity or excuse for such institutions as night or summer schools of medicine.

Both college faculties and examining boards have constantly to contend with too great variations in courses and times of study, and they would also gladly welcome some basis upon which to establish a more reasonable degree of uniformity. I would, therefore, again venture to suggest that a committee be appointed from this body with instructions to report at the next annual meeting, a curriculum and time of study which shall embody such features as, in their opinion, are demanded by existing conditions, and that the Association of American Medical Colleges be invited to be present when the report is made and to join in whatever discussion may follow.

EXAMINATION BY STATE MEDICAL BOARDS.

There is the widest range of variation in almost every leading point connected with the examinations made by

the state boards. The seven fundamental branches, of course, receive recognition from all, but when it comes to the special studies to be included in the examinations, such as pathology, bacteriology, biology, histology, neurology, psychiatry, gynecology, pediatrics, physical diagnosis, urinalysis, dermatology, rhinology, otology, laryngology, ophthalmology, venereal diseases and medical jurisprudence, they appear in all proportions. In the opinion of the writer there should be nine lists of questions, to include the seven fundamental branches, embodying in practice one or two questions each on pathology, neurology or psychiatry, bacteriology and medical jurisprudence, and, with surgery, questions on some of the following branches: dermatology, rhinology, otology, ophthalmology and surgical gynecology. There should be a list of ten questions in physical diagnosis, including urinalysis, making the eighth list, and five questions each on medical gynecology and pediatrics, making the ninth list. It is also of the greatest importance that a practical clinical examination should accompany and supplant, in part, the purely theoretical tests. No one can question the greater efficiency and justice of such practical determinations applied to either the recent graduate or the more experienced practician. Practical examinations of sputum, urine, blood and pathologic specimens can always be made available, and the clinical inspection of patients should be made possible and utilized. Some states do not indicate the branches on which their examinations are made, beyond the statement, "such as the board deems advisable"; others (as Virginia) prepare a list of questions, out of which the applicant can select and must answer a given number. So far as our observations have extended the questions given by all the various boards are fair ones, yet the examinations of some boards are more difficult than those of other boards. This is illogical, as the same skill should obtain in the examination and treatment of cases, irrespective of geographical location. There can be no adequate reason why the questions should not be more uniform in scope and severity. This change can be accomplished by devoting some time, at each annual conference of the state boards, to outlining and agreeing upon the extent and character of ensuing examinations. Such plan is feasible and should receive the earnest consideration of this body.

Adequate time should be given the applicant to make a full and complete answer to each question. Rapidity of thought and of its expression vary greatly, therefore the time allotted should be sufficient to meet the requirements of the slower thinker and writer. We find that some boards give but one hour in which to answer a list of ten questions, others an hour and a half, two, and up to three hours. It is evident to anyone having had experience as an examiner that no applicant can answer the average list of ten questions in one hour and do himself justice. Some may do quite well in two hours, but others, as proficient in knowledge, may have to curtail their work. We believe that three hours should be allotted for answering each list of ten questions, and that three such periods should be given each day until the examination is completed.

GRADING OF MANUSCRIPTS.

The grading of papers is one of the most important and exacting tasks which confront the examiner. It demands keen insight, mature judgment and ripe experience. While it may be true that no two examiners would place the same value upon each answer, still one is impressed by the uniformity with which a high or low grade applicant has been graded by various examiners. However, there are some points on grading to which your attention is asked.

Questions susceptible of being answered by yes or no should rarely, if ever, be used by examiners. It is very seldom that an applicant should receive 100 per cent. in any branch. Absolute perfection, implying that the answer embraces all that could be said on the subject, is almost impossible under the conditions attending a general examination. Some boards refuse a license to all below a certain per cent. in two or more branches; other boards when the general average falls below 75 per cent. (Massachusetts); and still other boards when the general average is below 75 per cent. (Ohio and other states). One state board (Washington) grants license to practicians of ten years' standing who attain an average of 70 per cent. or over; all others must average at least 75 per cent. We might go on showing more or less of variations among the majority of examining boards, but a basis of uniformity is more to our purpose. It is much easier for the applicant to attain a general average of, say 75 per cent. in all his papers than to reach 75 per cent. in each branch; yet, when the examination applies to both old practicians and recent graduates the basis of a general average possesses more of fairness, inasmuch as the man of experience should be proficient in the practical branches, so raising his grades, while the man just from college would maintain his standing by proficiency in the more technical branches. Every systematic method of grading has, doubtless, special advantages and also disadvantages. Our aim should be to establish one, the application of which will be attended with the highest degree of efficiency and justice. While there are advocates for each and every method of grading, may we not at least tentatively adopt a uniform standard—let us say a general average of 75 per cent., embodying as it does less of hardship and more of justice under the present condition of transition.

THE DISPARITY IN THE LAWS CAN BE OVERCOME.

The disparities in the medical practice acts and in their administration which have been referred to may, at first thought, seem difficult to harmonize, but such is not the case. The solution of this condition can be effected by the same means that has been applied to so many problems of modern existence, i. e., co-operation. The individual views of each board and of each member must be merged into the corporate views of a strong organization. Let the members of the confederation, after efficient investigation and exchange of views, agree to a uniform course of action, and in a very few years our laws would be in perfect accord. Any course that might be so adopted must be proved by strict adherence to its provisions, and as defects appear they should be remedied so far as possible. The result of such action by the confederation would be a stimulus to all reputable medical colleges to adopt uniformity in standards of preliminary education, curriculum, time of study, length of terms and methods of teaching. Their good standing would be jeopardized by falling below such standards. Colleges would thus have a basis upon which to establish their equality as educational institutions. Medical students would be greatly benefited by being placed upon the same legal standing in all colleges and states. Add to these conditions uniform state examinations, as hereinbefore outlined, and we have all the factors which are absolutely necessary to secure interstate indorsement of medical license. It is only by this perfected uniformity that such reciprocal relations can ever be established. The evolution of the process will

require time, as the ideas must be inculcated in the minds of legislators and civic officials as well as strongly ratified and upheld by the profession. The discouraging features in this great work are diminishing year by year. The beneficial effects of medical laws are more generally acknowledged and appreciated; there are fewer efforts to abrogate their provisions; the swindler and impostor have lost much of their power and influence, and the profession has developed strength. While the natural tendency of all laws is toward uniformity of application, we must not be content to simply hold aloof and criticise, but lend our best efforts toward its more speedy accomplishment. One of the greatest achievements in this work, already accomplished, is the uniting of the leading schools of medicine to secure necessary legislation. To-day we have the intense satisfaction of seeing them working side by side, imbued with the same high ideals of professional excellence and upholding the same educational standards. Can anyone say this is not substantial progress or doubt that much of what has been attained is due to this united action? Conditions change, and our modes of action must change with them. The demand now is for physicians and surgeons, not men imbued with sectarianism, pathies, fads or hobbies, but men of education, skill and high moral character; men that can meet upon the same plane and discuss matters with no other aims than the highest possible good for patient and public and the greater success of the medical profession. We meet here to-day, not for contention, but confederation. Our cause is just, its aims elevating. The efforts put forth to elevate the standard of scholastic attainment and personal character of the physicians and to protect the people from ignorant pretenders and swindlers, are not only making the profession stronger and more efficient, but raising American physicians in the esteem of other countries. Though the existence of this organization embraces but little more than the brief period of eleven years, its endeavors have been of great and far-reaching value in bringing about many of these beneficial results.

There is much yet to be accomplished, calling for our best judgment and earnest efforts, yet there is no one conversant with the history of medicine but must admit that a notable and substantial advance, from both scientific and sociologic standpoints, has marked American medicine during the past fifteen years.

While thoroughly conscious of the imperfection and inadequacy with which I have attempted to present some of the defects in our laws and in their administration, I earnestly trust that calling your attention to them may result in means for their correction. If, in considering some conditions, I may seem to have judged harshly or spoken inconsiderately, I must plead in extenuation my deep interest in the end to be attained.

Thanking you for the honor you conferred by making me the presiding officer of the confederation for the past year, also for the privilege of addressing you, I would wish you, both as an organization and individually, a year of usefulness and prosperity.

Sugar as an Exclusive Diet.—The Paris *Temps* has been publishing a series of articles on this subject. It recently received a letter from an engineer in South Africa, J. Jacquier of Johannesburg, who stated that during the late war he was caught between the two armies and was compelled to remain in his hiding place for six weeks with no food except a supply of sugar. He had six rabbits with him, and he fed himself and the rabbits exclusively with sugar mixed with sawdust. All thrived on it and the rabbits grew fat.

A NOTE ON MALARIAL VERTIGO.

THOMAS J. MAYS, A.M., M.D.
PHILADELPHIA.

That vertigo or dizziness develops in the course of malaria has been recognized occasionally, but the fact that this symptom may become so markedly accentuated as almost to claim for itself a distinct place in the nomenclature of disease, has been noticed by very few of our recent medical writers. Inasmuch as a number of such cases have occurred in my experience, it seems fit that I should briefly call attention to this important subject.

Malarial vertigo has been described by Triantaphyllides,[1] who states that vertigo may be intermittent or permanent, or merely a condition of dizziness, or it may be associated with other neuroses, but in a number of cases which he relates the vertigo could be attributed only to the malaria. There was no anemia, neurasthenia, dyspepsia, or any other manifestation of malaria, and the vertigo could be cured at once by hypodermic injection of large doses of quinin for four or five days. He attributes it to the probable alteration of the solar plexus by the malaria, similar to the gastric vertigo described by Trousseau. He states that the vertigo usually ceases when the patients recline, although in one of his cases compression of the sciatic and other nerve trunks induced the vertigo even when he was reclining.

Of the exclusive neurotic nature of this affection, as observed by Triantaphyllides, there is not the least doubt, as is well demonstrated by its principal symptoms, which will be considered in the following order:

VERTIGO.

This is the most prominent symptom of this disorder, and generally draws the patient's attention to his condition. In apparent good health he finds that his gait suddenly becomes insecure and unsteady, and he staggers as if he were suffering from alcoholic intoxication. In some of my cases this manifested itself so markedly that the patients fell to the floor, but in no instance was consciousness dimmed in the least. The attacks usually come on intermittently and during the day—in no instance have they appeared at night.

HEADACHE AND BACKACHE.

Headache is present in nearly all cases and is generally persistent. It sometimes alternates with a lightness of the head. There is frequently a fulness in the region of the occiput and neck.

Backache seems to be pretty constant in most cases and in some is of a very severe character. It is usually located in the lumbar region.

DEPRESSION OF SPIRITS AND EXHAUSTION.

Persons who in health are active and full of life gradually, and without good apparent reason, become moody and depressed, and tired and exhausted. The tiredness seems to be concentrated on the lower extremities below the knee, and is not relieved by sleep, since it is more prominent in the morning after rising than at any other time.

The bowels, as a rule, are costive, which is in all probability due to torpidity of the liver—a common condition in all forms of malarial poisoning.

HISTORY OF MALARIA.

In all the cases that came under my observation there was a well-defined history of intermittent fever, which had been more or less latent for some time, per-

1. Grece Medicale, iv, 6 to 9, as summarized in THE JOURNAL American Medical Association, May 17, 1902.

haps for years, before the appearance of the vertigo. In no case was the latter immediately preceded by a paroxysm of fever and ague. The heart and lungs were free from physical signs, and the pulse, respiration and temperature were normal.

Vertigo, in as severe a form as these attacks usually show themselves, leads to a great deal of anxiety and fear on the part of the patients and their friends, owing to the knowledge that this affection may pave the way for the outset of more serious nerve trouble. But if eye strain, gastric disorders, Meniere's disease and other prominent causes of vertigo, can be eliminated, and a clear account of previous malarial disorder be elicited, a favorable prognosis may at once be given and verified by appropriate treatment.

TREATMENT.

No remedy that I have administered in this disease acts more favorably and promptly than quinin in doses large enough to produce ringing in the ears. Indeed, the attacks of vertigo may develop while the patient is taking grain doses of the drug, but will vanish as soon as the dose is increased to eight or ten grains every three or four hours. Quinin will be more effectual when it is combined with strychnin, blue mass and capsicum than when given alone. The usual formula employed is:

℞. Quininæ sulphatis 3iiss
Pil. hydrarg. ..... gr. iv
Pulv. capsici ..... gr. ii
Strychninæ sulphatis ..... gr. i

M. Ft. capsulas No. xxxvi. Sig.: One capsule four or five times a day.

After the attacks have subsided smaller doses of quinin are to be administered in connection with strychnin and iron, interspersed occasionally with a dose of blue mass or calomel, the aim now being to enhance the digestive powers and to maintain the strength of the body. Any fresh manifestation of vertigo is to be counteracted with the larger doses of quinin and its combination given in the above formula.

VACATION NOTES.

G. FRANK LYDSTON, M.D.

Professor of Genito-Urinary Surgery, Medical Department, State University of Illinois; Surgeon to St. Mary's Hospital.

CHICAGO.

(Continued from p. 311.)

4. SYDNEY—NEW SOUTH WALES.

In a previous communication I qualified my enthusiastic description of the beautiful skies and placid seas of my Australian trip by stating that its serenity did not continue throughout. Between New Zealand and Sydney is a stretch of ocean which, for pure, unadulterated "cussedness," can not be excelled. When a sea captain of forty years' experience says that he is usually sick in crossing that bit of water, you would better take your troubles philosophically. Mark Twain has much to say of the extreme heat he experienced on his trip in "Following the Equator." He arrived in Sydney a week earlier in the spring than I did, and claims that the city was very hot, so hot that the doorknobs, which "melt in midsummer," were quite "mushy." I wonder what was the matter with Twain. I found flannels and an overcoat indispensable between Auckland and Sydney, and not uncomfortable in the latter place.

Having been forewarned as to what I might expect from Sydney Harbor, I was delighted, but not surprised, by the beautiful panorama which unfolded itself after our good ship rounded Sydney Head. Mere description could not possibly do the harbor justice. Completely landlocked, and presenting smiling bays extending in various directions, Sydney Harbor is peculiarly endowed both from the standpoint of scenic beauty and commercial facilities. It is well fortified, and a hostile fleet would have great difficulty in entering, even though it might possibly get near enough to drop a few shells into the town. It may be discourteous in me to say it, but the most beautiful feature of the harbor as I first saw it was Old Glory, flying from one of our Philippine transports.

It seems strange that a magnificent city of half a million inhabitants should have sprung up so far away from the great centers of civilization, and one must really see Sydney to fully appreciate the fact. With its clean streets, splendid public buildings—all in the best repair—and wonderful botanical and zoological gardens, this city may well be content with its comparative isolation. That the higher culture has not been neglected is shown by its magnificent art gallery, which contains a collection of paintings that any metropolis might covet. The only evidence that Sydney is not strictly up to date is the puff, puff of its dummy tram engines, and the absence of automobiles from its streets. The steam dummy and electric trolley on the same track are somewhat incongruous.

Medical Sydney is fully in keeping with the city's up-to-dateness in other respects. The Medical Department of the University of Sydney ranks with the best American schools. It was founded in 1883 and constructed at a cost of £80,000. The handsome structure is of the same style of architecture as the main university building, though, perhaps, not so ornate. The ground floor is devoted chiefly to the laboratories and practical class rooms of the departments of physiology and pathology, materia medica and medicine, and to a large anatomic museum. This museum, which was founded almost immediately after the commencement of the medical school, contains large numbers of normal and morbid specimens, and is an invaluable adjunct to the teaching appliances of the various departments. On the first floor are situated the dissecting room, measuring 51 feet by 41 feet, and five lecture theaters, of which the theater of physiology is the same size as the dissecting room, while the others are 45 feet by 36 feet, and each capable of accommodating about 200 students. Attached to the lecture room are the necessary preparation rooms. The basement contains, in addition to the caretaker's quarters, a laboratory for medical jurisprudence, and reading and luncheon rooms for the students. By the liberality of Lady Renwick, Dr. Sydney Jones, Dr. George Bennett, and Mr. John Harris, the building has been provided with stained-glass windows, while the corridor is adorned with busts of eminent physicians and surgeons historically arranged, all presented by private donors.

The hospitals of Sydney are something to be proud of. The principal hospitals are the Prince Albert—the most aristocratic and the most modern one—St. Vincent's and the Sydney. Prince Albert has a capacity of 230, St. Vincent's 130, and Sydney 316. These are all general hospitals and receive everything but contagious diseases. Prince Albert and Sydney hospitals are supported jointly by the government and private subscriptions. There is no special army and navy hospital. St. Vincent's Hospital is supported entirely by the Catholics. A new wing designed to accommodate 150 patients is in process of construction for Prince Albert Hospital.

The Sydney Hospital is the oldest in Australia (1845), but its present quarters are comparatively modern. The spacious buildings are built of brown stone, and their architecture is something to be remembered, even by an American physician who is used to the best in hospital construction. Its location is especially fine, the spacious hospital grounds adjoining the wonderful Botanical Gardens—Sydney's pride. The rear windows of the hospital overlook the gardens. The operating theater at Sydney is new and very much up to date, even to the point of pumping sterilized air into the room prior to and during operations.

The pathologic and *x*-ray departments of the hospital are its special features. Dr. Harris, who has charge of the skiagraphic work, stands third in the world as to experience in skiagraphs for renal calculi.

The Laboratory of Pathological Chemistry is equipped with apparatus which renders it possible to make use of the more

modern discoveries in physiologic and pathologic chemistry in their application to the improvement of diagnosis, prognosis and treatment in many cases which were formerly surrounded by almost insuperable difficulties and fallacies. Notably is this the case with some of the diseases of the digestive organs and, indeed, of metabolism in general. During the last few years certain methods of chemical analysis have been introduced which have led to a great advance in knowledge, and are, indeed, now gradually revolutionizing treatment. It is the distinction of the Sydney Hospital that to it belongs the honor of being the pioneer hospital of Australia, perhaps of the Southern hemisphere, in introducing modern chemical methods in diseases of the stomach, and metabolism generally.

The appendicitis work done at the Sydney is something to make one proud of American ideas and their adoption in alien lands. Radicalism is the basis of treatment. Cases operated on successfully are of course classified as cures, but it is very refreshing to note that cases of apparent recovery without operation are classified as merely "relieved." The general adoption of this classification would do much for surgical science and for humanity.

Sydney hospitals certainly can not complain of a lack of patronage. The total number of cases under treatment last year was 4,237. Of these 1,710 were accident or urgent cases. The number of operations performed during the year was 2,938, an excellent showing.

In the matter of accident or emergency work in general Sydney has really excellent facilities. A well-equipped ambulance brigade, with sub-stations here and there throughout the city, shows the acceptance of modern ideas in this far away part of the world. I say far away advisedly. Very few communities are so dependent on their own resources as is Australia. Reading European and American news six weeks old impressed this on me very forcibly. An infusion of American brains, energy and capital would make Australia a great country.

The staff of Sydney Hospital is as follows: Dr. C. V. Bowker, medical superintendent, the following gentlemen being associated with him as resident medical officers, viz.: Dr. Stacy, resident pathologist; Dr. Corbin, senior resident medical officer, and Drs. Cameron, Foster, Griffiths, Hart, Newman and Savage. The following gentlemen were the resident medical officers for 1902, viz.: Drs. Anderson, Ambrose, Coombes, Sharp, Seldon and Webb. Dr. Corbin and Dr. Cameron were the senior resident medical officers, with Dr. Griffiths as resident pathologist. Sydney Hospital has a large and efficient training school in which great attention is paid to instruction by the resident staff.

I inquired especially as to the genito-urinary service at the Sydney. The year's record was as follows: Circumcision 127, radical cure of varicocele 10, radical cure of hydrocele, 10, urethrotomy (external) 6, urethrotomy (internal) 13, dilatation of urethra 12, cystotomy (suprapubic) 4, cystotomy (perineal) 3, lithotomy 3, litholapaxy 5, opening of peri-urethral abscess 7, incisions for extravasation of urine 0, examination of bladder 2, removal of testicle 2, removal of calculus from ureter 2, prostatectomy 1, others 4, total 215. As may be observed, the service in this special department is light. Indeed, it would make a pretty small private practice for an ambitious man. The gynecologic department fares but little better. The yearly record is as follows: Abdominal section for ovariotomy and oöphorectomy 31, ectopic gestation 15, tubo-ovarian abscess 6, pelvic abscess 6, multiple abscess of broad ligament 0, ventrofixation 2, ovarian cyst 4, pyosalpinx 18, hysterectomy (abdominal) 10, hysterectomy (vaginal) 1, vaginal celiotomy 24, curettage 48, trachelorrhaphy 1, perineorrhaphy 3, Alexander's operation 23, repair of vesicovaginal fistula 2, total 216. The paucity of hysterectomies is especially noteworthy. A large general hospital with only one vaginal hysterectomy in a year—think of it!

Sydney is a city of contradictions, away behind the times in some few things, but in most it is worthy of emulation. Medically and surgically little exception can be taken to its status. There is not a decent eating house in the entire city of half a million inhabitants; if you want your shoes blacked you must go to a hotel and get out a search warrant for a porter, who wonders why you didn't have them polished twice during the previous night; if you want to quench your thirst or take a bath you are warned of the dangers of drinking the water, and instructed by the city to take a shower, not a tub, bath because water is scarce; but you can ride on a municipal tramway, and that is a great thing. The street cars, or trams, are run by the city and on the sectional system. The greatest distance costs three pence, and you can ride two miles for two pence. The employes work only 8 hours, and are well treated and well paid, yet the tram system netted £39,000 last year. This is something worth thinking about, all ye corporation-ridden American cities.

Sydney is not a suitable health resort for victims of insomnia. The postoffice clock and several rival sets of chimes vie with each other in the making of noise. The bell of the clock is a terror, and, to prepare its victims for the ordeal of listening to the striking of the hours, the various chimes play: "God Save the King." Then leaving Providence to deal with the king as best he may, the chimes retire for a spell and give a fair field and no favor to the clock: "Boom! boom! boom!" it goes and away flies balmy sleep. Just as you begin to doze, fifteen minutes later, the king gets into deep trouble again, and the chimes proceed to save him some more. And then you determine to economize nervous energy by remaining awake. Of one thing I am certain, the Sydney chimes save enough kings every day to insure England's line of succession for centuries. England should have a full hand of kings by this time. All the same I think it mean of Sydney to try to monopolize God's time. We need some "saving" in America.

Sydney has recently gone through its second epidemic of the plague. Much valuable knowledge has been gleaned by the local health board of Sydney. The epidemic just passed through was the second which Sydney had experienced. It afforded the first opportunity the world has had of studying plague occurring among white population and under modern scientific methods. The chief health officer, Dr. Ashburton Thompson, is a man of great ability and zeal and his industry is phenomenal. Simond's theory of the dissemination of plague by fleas from plague-stricken rats has been adopted as a working theory, and, as Dr. Thompson naïvely remarked, the health officers are supervising the health of the Sydney rats, rather than that of its people. The last plague rat was caught July 14 last. Since June 4,500 rats have been examined in the laboratory of the health board.

(To be concluded.)

Clinical Report.

FLY LARVÆ IN THE EAR.

GEORGE F. POPE, M.D.
RED LAKE, MINN.

August 25 there appeared at my office a man, 26 years of age, who seemed much agitated. He explained that he felt snakes in his right ear. By the aid of direct illumination I observed close up against the ear drum and in the canal just below it what appeared to be a mass of writhing white larvæ. Some of them were wiggling in a circular manner about the canal close to the drum membrane, but none ventured toward the external opening.

The rays of light from the mirror seemed to increase their movements and cause the patient greater pain and excitement. I therefore discontinued my examination and introduced a small pledget of cotton saturated with chloroform just within the canal. The movements of the larvæ soon stopped, as shown by direct illumination, so I syringed out the ear with warm water and got 21 dead larvæ. On undertaking a more careful examination of the drum I found an old scar in lower posterior quadrant, but failed to get a history of otitis-media.

The larvæ were sent to Prof. Louis Leroy of Vanderbilt University, Nashville, Tenn., for examination. He reports them to be from one of the common house flies. He informs me that they usually occur in ears in which some discharge of pus has been taking place.

INTRAVASCULAR INJECTIONS OF FORMALIN IN SEPTICEMIA.

A case of puerperal septicemia recovered after the intravenous injection of formalin solution. We are told that the case was regarded as hopeless and that the effect of the formalin injection was "magical." This episode has been exploited in a sensational manner in the daily press and it has been heralded in medical journals as a discovery and an epoch in the history of medicine. While all would welcome the demonstration of a successful treatment of septicemia, there is unfortunately the very best of reasons for questioning the correctness of the inference that the recovery in the case referred to resulted directly or indirectly from the injection of formalin. The reasons for this doubt may be presented under two heads, namely, (1) the now well-known occurrence of spontaneous recovery from various forms of septicemia, or blood poisoning, and (2) the inadequacy of available evidence to show that formalin solution has any bactericidal or curative effect when introduced into the circulation of infected animals in nonfatal doses.

Every physician of experience has had the opportunity to observe apparently "hopeless" cases of septicemia suddenly change for the better and perchance after a remission or two go on to recovery. The bad prognostic significance formerly and even now attached to the diagnosis of septicemia or blood poisoning is sure to undergo considerable modification as the results of bacteriologic examinations of the blood during life and according to approved methods become more generally known. It has been shown conclusively that cases of bacteriemia, be it streptococcemia, pneumococcemia or staphylococcemia, may recover spontaneously even when the blood has been found to contain large numbers of bacteria, and even when metastatic foci, such as articular inflammations and endocarditis, have developed. This being the case, the recovery in a single, isolated instance of streptococcemia injected with formalin proves little or nothing in regard to the value of the latter. For aught we know it might be nearer the truth to say that recovery resulted in spite of the formalin injections. We can not regard the puerperal septicemia "as an otherwise fatal condition." In 47 cases of bacteriemia, demonstrated to be such by cultures from the blood during life by Bertelsmann,[1] death took place in 26. In this series there were 28 cases of streptococcemia, and of these 13 died. Other examples of this kind could be cited. Recently Herrick[2] has collected a number of cases from the literature of recovery after undoubted malignant endocarditis. He is fortunate enough to furnish the anatomic proof of the healing of ulcerative endocarditis in three cases in the form of healed valvular perforations. In view of these facts it is self-evident that the actual value of formalin injections in septicemia can be determined, from the clinical standpoint, only by systematic use in a large series of cases under careful control by persons capable of sober judgment.

Coming now to the experimental study of the curative and bactericidal action of formalin solutions in infected animals, then we may say, in brief, that the results so far are not at all encouraging. Fischer and Tieken[3] found that repeated intraperitoneal injections of formalin, 1/2000 or 1/1000, in doses of from four to eight cubic centimeters, had an unfavorable influence in guinea-pigs with peritoneal tuberculosis. The injected animals were less able to resist the tuberculous infection than those not injected. Fortesque-Brickdale[4] found that formic aldehyd in large doses so depresses animals infected with pneumococci that they die sooner than an untreated animal used as control. Formalin, i. e., formaldehyd, according to Waldemar Koch,[5] interferes with the normal proteolytic processes in the cells, and hence it would tend to reduce rather than strengthen the cellular resistance to noxious agents. Certainly not much may be hoped from the use in human septicemias of an agent that has proved so disappointing in animal experiments.

Pending scientific investigation, an emphatic caution should be given to the general practitioner. Six or more cases in which this agent was used are already reported in the newspapers, and most of these trials were undoubtedly suggested by the accounts of Barrows' case in the lay press. This indicates the eagerness of the profession to avail itself of any hope of relief in a desperate condition. The trial should certainly be left to cases *in extremis*. Barrows[6] warns the profession against indiscriminate use of this agent where proper blood cultures have not been made to determine the cause of the septicemia.

The technic of the injection is simple—that of any intravenous infusion and with all the usual surgical precautions. The solution used has been of a strength of 1 to 5000 of formalin in physiologic salt solution. As much as 750 c.c. have been injected. In determining the results the value of injections of physiologic salt solution itself, either with or without abstraction of some of the sepsis-laden blood, should be remembered. Control experiments would be of exceeding value in such cases if they were possible.

CYTOTOXINS AND HEREDITY.

Aside from metaphysical and recondite distinctions with which the subject has been somewhat obscured, the question of heredity of disease may be stated as follows: Can parents, apart from direct antepartum or postpartum infection, transmit their diseases or defects to their offspring? As regards most germ diseases it is coming to be generally believed that they are not thus transmitted save in very exceptional cases, otherwise than through direct parental infection either after birth or during fetal life. In some cases where no parasitic origin has been definitely established, it is still assumed that such exists and that the same rules apply. While it is still largely recognized that in some diseases a predisposition may be created, yet even this is being questioned by some, and the favorite theory of germ transmission is invoked to account for the conditions existing. One does not have to look far in medical literature to find this tendency; it is not yet predominant perhaps, but it seems to have grown in favor of late years. The burden of proof has been, in a measure, shifted from the advocates of infection in a large class of disorders heretofore reckoned as due to transmitted anomalies of metabolism to those who would still maintain their constitutional and hereditary character. The influence of heredity has been minimized even in nervous disorders and insanity in some quarters, notwithstanding the very obvious evidence of its existence. Bacteriology and certain theoretical biologic views seem to have very largely discredited heredity—at least with some medical writers and thinkers. The sins of the fathers, they hold, are not visited on the children to the third and fourth generation, except in some vague way of impairment of the germ plasm or through the direct agency of infecting microbes.

To the average practitioner, however, there is still a reasonable probability of the inheritance of disease; it is the most natural way of accounting for clinical facts of daily experience. What we need is more thorough studies of the phenomena of degeneration as shown in the offspring of diseased parents and of their correspondence with the original lesions of the progenitors. The inheritance of a predisposition to a special disease would seem to imply a special weakness of the organs involved or lack of resistance to a special microbic agency, which is in reality not so essentially different from the actual inheritance of the disease itself. The distinction is more a metaphysical than a practical one.

In a lecture[1] recently delivered at the College de France, M. Charrin discusses this subject at length and gives the results of special studies as to the part played by the soluble toxins in the transmission of pathologic taints. He found that the fetal cells are directly influenced in their structure, function and secretions by paternal and still more by maternal disease so that it is difficult to avoid seeing the relation between them, and this without bacterial infection or, at least, without any characteristic species and without any causal factors in the environment. Instead of vaguely speaking of "the soil" or "the predisposition" Charrin thinks that we should discriminate between the various morbid manifestations which result from pathologic taints in the progenitors. He has been able to determine a deficient alkalinity in the plasma or an increase in the toxic substances in the humors in the infants of diseased parents. He has also observed in these or other infants a tendency to hypothermia capable of inhibiting phagocytic action. He gives the details of his findings in a number of cases and proclaims that it is necessary in each case to seek for the exact pathologic taint in the infant and counteract the morbid tendency by special, appropriate measures. He has been conducting much clinical and experimental research in regard to the transmission of cytotoxins, and thinks that such soluble substances play a very important part in the transmission of morbid tendencies. Among the experiments related is the subcutaneous injection of an emulsion of liver substance in a gravid goat. A total of 84 gm. was injected at various times, equal to 2 per 1000 of the animal's weight. Sixteen days after the last injection she was delivered of a kid that died at once. All its organs were macroscopically sound with the exception of the liver, which was reduced to a pulp. There were no traces of microbes. It is not difficult to conceive after witnessing such experiments that the disintegration of a tuberculous lung in a pregnant woman might lead to the production of a pneumotoxin. This pneumotoxin, passing through the placenta, might have an injurious influence on the development of the embryonal lung, not inducing necessarily any decided lesions, but preventing its full normal development. The lung in the offspring, therefore, would always remain a weak point. Such facts suggest an explanation for the fact that in certain families the liver is affected generation after generation, in others the heart or kidneys. More than this—we already know the mode of action of the lysins: they induce the production of or incite to action the alexins, complements, sensibilisatrices, etc. We also know how to combat them by inducing the production of antisubstances. There is thus a prospect that we may be able by this means to institute effective therapeutics based on our knowledge of the pathogeny.

M. Charrin's article is suggestive in many ways; we have given only a brief review of some of its leading features. The field of study it points out is apparently one well worth cultivation and one that may be fruitful in resolving some of the obscure problems of biology as well as giving possible direct practical results in the therapeutics of disease.

1. La Semaine Med., No. 51, Dec. 17, 1902.

COLOPEXY FOR EXTENSIVE RECTAL PROLAPSE.

Prolapse of the rectum as so frequently met in children usually yields to palliative measures even if the prolapse be very extensive; on the other hand, the treatment of prolapse in adults is far from being such an

easy matter, as can be seen by the numerous methods of operative treatment which have been advised. Many factors tend to produce prolapse, the most important being relaxation of the rectum, of the pelvic floor and of the sphincter. When there exists with this constipation and resulting straining at stool, the condition rapidly becomes aggravated enough to demand operative treatment.

Among the measures which have been suggested are various methods of narrowing the anus and of reducing the relaxation. The use of the actual cautery to produce cicatricial contraction has not been followed by satisfactory results, so far as cures go, and in some cases of extensive prolapse has been followed by perforation with fatal result. The method of narrowing the rectum by torsion of the intestine, as suggested by Gersuny, is frequently followed by failure. Excision of the mucous membrane, as in Whitehead's operation, is a simple operation, not accompanied by much danger, but which has failed to give permanent cures. Resection of the prolapse, as specially advocated by Mikulicz, has in the past been considered the most reliable method of treatment, although the operation is extensive and accompanied by some danger. This should be undoubtedly the operation of choice in those cases in which the prolapse is strangulated or in which there is extensive ulceration.

Suspension of the intestine is a method which has come into use very recently, and has been specially recommended by Ball of Dublin, whose Lane lectures on rectal surgery in San Francisco were recently listened to with so much profit. Von Eiselsberg[1] of Vienna has published the results of colopexy, or suspension of the colon, in 13 cases, and from his experience he believes with Ball that this is the method of choice in the treatment of extensive rectal prolapse. He finds that resection and the various methods of narrowing the lumen of the intestine or anus are unreliable, recurrences following frequently. Moreover, the operation of resection is severe enough to be followed by a considerable mortality. Colopexy may be performed through a small incision in the left side, not larger than that required for an exploratory operation. The prolapse is not only replaced, but drawn up so that the anus has a funnel-shaped appearance, and two or three rows of silk sutures fasten the denuded wall of the colon to the abdominal wall. He keeps his patient in bed from three to five weeks following the operation. The operation in his hands has not resulted fatally in any case. Recovery has been uneventful, and the permanent results entirely satisfactory except in two cases, in which the patients were, however, considerably relieved.

This operation has not come into very general use in this country. The advantages which it offers and the satisfactory results which have followed in the hands of reliable men, seem to commend it as an operation deserving to be much more generally employed.

1. Archiv für Klinische Chirurgie, 1902, vol. lxvii, page 745.

THE METRIC SYSTEM AND MEDICAL SCHOOLS.

It is now more than twenty years since the metric system was first indorsed by the American Medical Association. Within that time it has become more or less familiar to the medical public of this country, but its adoption is yet far from being accomplished. It is a difficult thing to supplant old habits, and all the conservatism of human nature comes into active play in such cases as the adoption of a system which not only in its medical, but in almost all other relations of life would require a change in our habitual conceptions and usages. Nevertheless, there are many physicians, though perhaps fewer just now than some years ago, who use this system in their prescription writing. It would be well if the practice were more general. The advantages are obvious, it would put us on the same footing with physicians throughout the greater part of the civilized world. Only in the English-speaking countries is the metric system not the usual one employed. We are constantly required to understand the meaning of grams, centigrams and cubic centimeters in our medical literature, with sometimes awkwardly confusing results; and serious mistakes have not been always avoidable because of the lack of care in properly stating the signs for grams and grains.

The change would not be a difficult one to the physician, and we believe there are few druggists who would be unable to adapt themselves to the newer system without serious difficulty. We can easily see the drawbacks in large economic industrial establishments where the sudden change of systems, it has been calculated, would cause a very great expense, reaching thousands of dollars in special establishments and manufactories. This, however, does not apply to the medical side of the question, where the change would be comparatively easy. The indorsement given by the Association has been repeated more than once, and there is just as much reason for it at the present time as ever. The public is already half educated to the change. It would take but little more for us as physicians to make it complete.

It may be that the solution of the question rests with the instruction in medical colleges. If the metric system were used primarily in them and the old apothecaries' weight only incidentally, instead of the reverse, as at present, the newer generation of doctors would perhaps go out metric habitués—so to speak—and the usage of the really more scientific and convenient medical notation come to be the rule. The text-books would then be obliged to follow suit. At present there is often a sort of lurking suspicion that metrically-written prescriptions may not be properly dispensed. Of course, with educated pharmacists there should be no question, but the suspicion undoubtedly exists and must be overcome. In the physician unused to the metric system his uneasiness is perhaps born of his own lack of knowledge. A little more attention to the subject in the medical schools would, we think, do away with this doubt. A disuse of

the old apothecaries' weights in the common school text-books would also be a help, but can hardly be expected as long as they are so universally in use. But when the physician and pharmacist cease using the old complicated weights, who else will want to use them? It is to the medical schools that we must probably look for the real initiation of the reform.

DECEITFUL TRADEMARKS LOSE THEIR PROTECTION.

The United States Supreme Court has recently given out a decision which has some bearings on medicine. The case at hand is that of a California medicine company against another patent medicine company for infringement on its trademark. It went through the various courts and finally reached the United States Supreme Court and was fully argued. In the opinion of Justice Shiras it was held that if any symbol or label claimed as a trademark is so constructed as to contain any distinct false assertion its exclusive rights can not be maintained. If the plaintiff makes any material false statement, says the court, in connection with the property which he seeks to protect, he loses his right to claim the assistance of a court of equity. Any advertising trademarks, therefore, for quack medicines with extravagant assertions or claims are hereafter useless.

DO MANUAL INJURIES DISABLE PHYSICIANS?

A physician is not a manual laborer, but the use of his hands is about as essential to him as it is to the larger proportion of the class that earn their living by their daily work. This, however, does not seem to be the view taken by an insurance company. An accident insurance company was sued to recover a disability policy by a physician who had his hand badly cut and was for several weeks deprived of its use. The special claim was made that he was prevented from performing several surgical operations. He simply asked for the $5 per week disability which the policy promises. In its reply the company, with the usual evasiveness of too many business corporations, claim that a physician is not disabled by any manual injury, but that he earns his living by the use of his brain. It thus apparently altogether ignores the claims of loss from disability to perform surgical operations. Of course, this is a matter that probably will not go beyond the court and will be quickly settled, we believe, to the discomfiture of the company, but the claim is a new one—that manual dexterity is of no value to a physician—and shows how business corporations as well as other organizations of individuals endeavor to exploit the medical profession.

THE PHYSICIAN AND THE PHARMACOPEIA.

It looks as though we were to have a reaction in the medical profession from the use of proprietary remedies and polysyllabic compounds to the employment of the simple but officinal drugs and compounds of the United States Pharmacopeia. It can not be denied that too many physicians are unfamiliar with that valuable work. Created by the medical and pharmaceutical professions, it has always been recognized by the pharmacist as a reliable and official guide, but to the physician it has been too often an unknown work and one seldom found on his book-shelves. Wilbert,[1] in a timely article, lays some of the blame for this unfortunate condition to the enormous increase in proprietary medicines, which have become, he says, an unmitigated nuisance. He notes with satisfaction, however, the return on the part of the ablest medical men to the use of the simpler but more efficient and safer remedies of the Pharmacopeia. Therein are described drugs and combinations of drugs to meet every therapeutic indication, while "among the untold thousands of patented preparations not a single one has been demonstrated to be able to produce any physiologic phenomena that can not be produced by one or more substances readily available in the ordinary channels of trade." There is a need in the literature of the day for more discussion of the common remedies and their therapeutic uses, such, for example, as is suggested by our Therapeutic department January 17, where sulphur is recommended as of value in many and various conditions. If the physician would study his Pharmacopeia more and proprietary circulars less, it would be better both for himself and for his patients and for the pocket-books of both. Wilbert further speaks of the recent Congress for the Unification of Heroic Remedies, and urges that the suggestions for international standards ought to be incorporated in the Pharmacopeia. The publication of the next revision may be expected in about a year, he says, and if medical societies should at once express themselves as in favor of such a course the revision committee would include the standards. This would be a long step toward their international adoption, which is so much desired.

Medical News.

CALIFORNIA.

To Ward Off Disease.—A bill has been introduced in the State Senate appropriating $100,000 for the use of the State Board of Health, to ward off contagious diseases.

Resort for Semi-Invalids.—Through the beneficence of N. O. Nelson of St. Louis, a resort for semi-invalids has been started at Indio in the Coachella valley. He has bought 127 acres of land, and will erect a central building and a number of cottages.

Polyclinic Election.—The trustees of the San Francisco Polyclinic have elected the following officers: President, Dr. George W. Merritt; vice-president, Drs. John Wilson Shiels and Henry L. Wagner; secretary, Dr. Martin Regensburger, and treasurer, Dr. Louis Bazet.

Smallpox.—At Big Sandy 10 cases are reported among the Indians. Kingsburg has had 51 cases, but the disease is now under control. In Fresno there are 10 cases at private houses and 4 in the county isolation hospital. Redding has had 3 cases. The disease, which was apparently epidemic in Tulare, is disappearing.

The Mortality of Los Angeles.—During 1902 there were in Los Angeles 2,290 deaths, about 300 more than in 1901. The death rate per thousand—16.96—is relatively high, due, as the health officer explains, to the immigration of patients in advanced stages of tuberculosis. Tuberculosis was the cause of 484 deaths, and of these 366 had been in Los Angeles less than 10 years, and 212 less than one year.

In Trouble.—Dr. Ralph A. Huntington, San Franciso, who was convicted Feb. 20, 1901, of manslaughter for causing the death of Miss Jennie McKown and was sentenced to serve the maximum term of ten years, has been granted a new trial by the Supreme Court.——"Drs." William Davis and H. L. Meyers, "oriental healers and seers," of Los Angeles, have been

1. The Physician and the Pharmacopeia. M. I. Wilbert, Ph. G., New York Medical Journal, January 3.

arrested for conspiracy to defraud.——Sylvester W. Richmond, a "layer-on-of-hands," of Los Angeles, has been convicted of practicing medicine without a license.——Julia S. Tickel, Fresno, is under indictment for alleged unlawful operations.

Personal.—Dr. Matthew Gardner, San Francisco, has been appointed a member of the State Board of Health, vice Dr. Walter B. Coffey, resigned.——Dr. Frank P. Wilson has been appointed assistant city physician of San Francisco.——Dr. George Chismore, San Francisco, was recently injured by a collision with an automobile.——Dr. Zemach Levin, San Francisco, has returned after six months' study in London and Berlin.——Dr. Edwin A. Kelley, Berkeley, has been appointed second assistant physician at the Agnews State Hospital for the Insane.——Dr. William N. Moore, Ukiah, has been appointed a member of the local board of health, vice Dr. Samuel L. Rea, resigned.——Dr. J. Coplin Stinson, San Francisco, has been appointed a member of the board of health.

DISTRICT OF COLUMBIA.

Returned from the Philippines.—Dr. Thomas C. Chalmers, major and surgeon, U. S. V., was honorably discharged from the medical service February 1. He will take up practice in New York City, and has been elected surgeon to the Twelfth Infantry, N. G., N. Y.

Health of the District.—The report of the health officer for the week ended January 28 shows the total number of deaths to have been 114, of which 69 were white and 45 colored. At the close of the week there were 148 cases of typhoid fever, 13 of scarlet fever, 13 of diphtheria and 7 of smallpox under treatment.

For School Medical Inspectors.—Senator Gallinger has offered an amendment to the district bill providing for 11 medical inspectors for the public schools to be appointed by the board of education, each at a salary of $500 per annum. Eligibility for appointment is based on five years' practice of medicine in the district and a competitive examination.

Resident Physicians Appointed.—At the competitive examination, held January 24, to fill vacancies in the house staff of the Central Dispensary and Emergency Hospital, Drs. John T. Dunn and W. Robert Perkins of the District of Columbia were successful and will become senior and junior assistant resident physicians. Dr. F. H. Warhart, the resident physician, retired February 1 and was succeeded by Dr. J. H. Cashman. Dr. Richard Lightburn Sutton, Kansas City, Mo., the former resident physician, has successfully passed a competitive examination and has been appointed first lieutenant and assistant surgeon in the Navy.

Hammond Relief Bill.—Senator Elkins has introduced a bill to amend the act approved March 15, 1878, so as to appeal the provision that Dr. Hammond should not be entitled to pay while on the retired list of the Army and providing that he shall be entitled to the pay of brigadier general on the retired list from the date of his appointment and retirement under said act, Aug. 27, 1879, up to the date of his death, Jan. 5, 1900, the same to be paid to Esther D. Hammond, his widow. The general impression is that the bill should and will pass and become a law. Mrs. Hammond is prominent in society, and an active member of many prominent charity organizations of the district.

Hospital Appropriations.—Senator Stewart has offered an amendment to the sundry civil bill appropriating $100,000 for the reconstruction and completion of the Providence Hospital. A modern morgue is to be added and the approaches to the hospital graded.——Senator Gallinger has offered an amendment to the district bill appropriating $75,000 for the erection of an additional building to the Homeopathic Hospital.——Senator Mason has offered an amendment to the same bill appropriating $200,000 for the erection of new buildings for the Freedman's Hospital. Two hundred patients will be accommodated in the extension, and it is provided that the Howard University shall furnish, from its medical department, free of cost, a medical staff.

Committee on Public Health.—Dr. D. Percy Hickling, chairman of the committee on public health of the board of trade, presented his report at the recent annual meeting of the association. It showed a large amount of valuable work done during the past year and contained a number of valuable recommendations, including general hygiene of the District, prevention of diseases, provision for public baths, public houses of convenience, and medical supervision of schools. Dr. Kober addressed the meeting, discussing general health conditions. Surgeon-General Sternberg read a paper on the prevention of tuberculosis, its origin and treatment. Dr. W. C. Woodward discussed the health needs of the District. Mr. Weller, secretary of the Association of Charities, delivered an illustrated lecture on the slums and disease-breeding localities of the District.

New Army General Hospital.—The new Army general hospital recommended to congress by the Secretary of War, to be established in the District of Columbia, is designed to serve as a base hospital in time of war, and to be so situated as to permit of immediate and temporary enlargement. On the outbreak of war troops would be assembled in the vicinity of Washington and there would be immediate need for such a hospital. This hospital is to form part of the equipment for the Army Medical School, enabling the student officers to become familiar with the method of administration, hospital inspection, the use of the Roentgen rays and other diagnostic apparatus, and to receive instructions in medical and surgical procedures having special application in the military service. The hospital will also have facilities for the practical training of the hospital corps and the army nurse corps. The staff will be composed of army medical officers having a special knowledge of surgery, diseases of the eye, ear, throat, etc., and special equipment will be provided for the treatment of such diseases. The need of such a hospital was evident during the recent war and a general hospital on a small scale was established at Washington Barracks, but this establishment has been found inadequate in size, and it can not be increased, as the ground is required for the erection of buildings for the Army War College at the post. Since this hospital was established in 1898, 3,000 hospital corps men have been trained and sent to military posts in the United States, Porto Rico and the Philippines. Hundreds of successful operations for hernia have been performed, thereby saving the government thousands of dollars in pensions. The student officers have had the benefit of hospital training in all its branches.

ILLINOIS.

An epidemic of measles at Taylorville is reported; 300 cases exist and 10 deaths have occurred.

Springfield Hospital staff has elected Dr. George F. Stericker, president, and Dr. R. Dillard Berry, vice-president.

Hospital for Waukegan.—Through the liberality of Mrs. Jane McAllister Waukegan is to have a new hospital to cost $20,000, which Mrs. McAllister will also equip.

In Memory of Dr. Kohl.—The St. Clair County Medical Society, at a special meeting in Belleville, adopted tributes to the life and character of its late member and president, Dr. Julius Kohl.

Dr. Murphy's Estate and Bequests.—The will of the late Dr. John Murphy, Peoria, devises an estate appraised at $400,000. St. Francis' Hospital, Cottage Hospital, Home for the Friendless and Home of the Good Shepherd, each receives $5,000.

Personal.—Dr. John F. Snyder, Virginia, has been elected president of the Illinois State Historical Society.——Dr. William R. Patton, Charleston, was thrown from his buggy, January 26, and dislocated his left shoulder.——Dr. William F. Grinstead, Cairo, left on February 1 for a trip of four months in Europe and the Holy Land.

To Create Tuberculosis Sanitarium.—Representative Hardin has introduced a bill to create a state sanitarium for the scientific treatment of persons afflicted with tuberculosis. The bill provides an appropriation of $200,000 for the institution and creates a board of trustees consisting of three members, one of whom is to be a physician.

Chicago.

Rupture Specialist in the Toils.—Edwin E. Rohrabaugh, an itinerant hernia specialist of Chicago, was recently arrested in Des Moines. The grand jury has found a true bill against him on the charge of violating the law whereby itinerant physicians in Iowa are required to pay a special license fee.

Deaths of the Week.—During the week ended January 31 586 deaths occurred, 35 more than in the preceding week and 69 more than in the corresponding week of 1902. Pneumonia caused 104 deaths; consumption, 52; bronchitis, 32; heart disease, 46; Bright's disease, 41, and violence, 42. The annual death rate per 1,000 for the week was 16.20.

Alexian Brothers' Hospital.—The annual report of the Alexian Brothers' Hospital shows that in 1902 2,981 patients

were cared for, of whom 1,912 were discharged cured. Of 305 who died during the year 122 were admitted to the hospital in a dying condition. Of all the patients treated, 1,681 paid fees in full, 397 paid partially, and 903 were treated gratis.

Smallpox.—During January 50 cases of smallpox were reported. Of these 24 were negroes; 24 had never been vaccinated. Only 6 had marks indicating previous vaccination, and these were old. An interne at the County Hospital was one of the infected. He was 30 years of age and had an old atypical scar. Of the 50 patients 11 were from points outside Chicago.

Founder's Day at Northwestern.—The alumni of Northwestern held their third annual banquet, January 27. Dr. William W. Keen, Philadelphia, was one of the guests of honor, and the arrangements were in the hands of Dr. Winfield Scott Hall. President Hadley of Yale delivered the address at the closing exercises on "The Place of the Professional School in the Modern University." The honorary degree of Doctor of Laws was afterward conferred on Dr. Keen.

Coal Famine and Mortality.—The department of health in its *Bulletin* for January 31 considers that the increased mortality for January is due directly to the shortage of coal.

Unrevised returns of mortality for the month of January, 1903, show an increase of 10.4 per cent. (or 344) in the actual number of deaths from all causes and at all ages, and of 11.4 per cent. in proportion to population, as compared with January, 1902, when coal was abundant at one-half the price or even less than that it now commands—when it can be obtained at all. These two facts are cited together because, in the judgment of the health department, the latter is the principal if not the sole cause of the former. A large proportion of the excess deaths is, as was stated in the *Bulletin* of January 10, due to cold and exposure caused by the coal famine, and which at that date had affected the health of fully 10 per cent., or nearly 200,000 of the population of the city. Had any other one cause so seriously menaced the public health and welfare a grave emergency would have been declared to exist, authorizing the exercise of the plenary power of the municipality under the warrant and law of "overruling necessity."

MARYLAND.

Baltimore.

Vital Statistics.—Pneumonia is largely prevalent, it is believed owing to the epidemic of measles. Of the 242 deaths reported last week, 47 were ascribed to it, while bronchitis caused 7. There were 204 new cases of measles reported, with 5 deaths, and 40 new cases of diphtheria were reported. The deaths reached the high rate of 23.02 per 1,000 per annum.

Magness Reindicted.—Dr. Thomas H. Magness, who was indicted at the last term of court at Parkersburg, W. Va., charged with taking the state medical examination there last spring in the name of David Shepler of Bellevernon, Pa., a student of the Baltimore University, of which Magness was then resident physician, and of personating the said Shepler, was indicted again January 27, the former indictment having been quashed on account of a technicality.

The Frick Library.—The Charles Frick collection of the Medical and Chirurgical Faculty now numbers 2,209 volumes. There were added during 1902 273 volumes, chiefly English, French and German works on diseases of the kidneys and internal medicine. Increasing appreciation of this collection is shown, 2,223 volumes being taken out for home use and 4,510 readers being registered during the year. A valuable addition lately made through Dr. Osler is a remarkable collection of theses by American students at the University of Edinburgh between 1760 and 1810. The Frick fund for 1902 included $500 from Mr. William F. Frick, $50 from Mr. Frank Frick, and $200 from Mrs. Dr. H. Barton Jacobs. In addition to this was the membership of the Book and Journal Club, amounting to about $500. This club, organized seven years ago, has contributed about $3,000. The above funds are devoted exclusively to the purchase of new books and the more expensive journals, while the appropriation set aside by the faculty is used for running expenses, and the larger bills for journals and binding.

Wood Alcohol Poisoning Case.—The trial of the wood alcohol poisoning case in the Baltimore Court was the leading medical feature here last week. The court refused to admit the analysis of Jamaica ginger made by the drug firm two years after the alleged poisoning. He also refused to take the case from the jury and decide it himself. A former employe of the drug firm testified that the latter used wood alcohol in the preparation of Jamaica ginger from 1897 to 1900, the proportions used being: wood alcohol 30 per cent., grain alcohol 50 per cent., and water 20 per cent. The attorney for the defense acknowledged that this proportion was correct, and that in the three years 65,376 bottles of the preparation were placed on the market. Drs. Herbert Harlan and Hiram Woods testified that Dr. Brehm's loss of sight was due to wood alcohol. Dr. Charles A. Crampton, a government chemist employed in the internal revenue department; W. A. Puckner, professor of pharmacy in the University of Illinois, and F. P. Kuehne, a manufacturer of flavoring extracts at St. Louis, testified that wood alcohol, in their opinion, was not poisonous.

MASSACHUSETTS.

Gifts to Harvard Medical School.—During 1902, $727,845 was given to Harvard University for capital account, and $367,891 for immediate use. For the medical school John D. Rockefeller gave $308,758, subscriptions were made amounting to $189,024, and for the George Higginson professorship of physiology, $100,000 was given by Mr. Higginson's children.

Alleged Operation Without Consent.—Suit has been brought by an aged Charlestown woman against Dr. Samuel J. Mixter, Boston, for $2000 damages. The plaintiff alleges that Dr. Mixter operated on her without having obtained her consent, and that in consequence she has since continually suffered and will continue to suffer, besides having been put to great expense.

Epileptic Hospital Report.—The trustees of the Massachusetts Hospital for Epileptics, Monson, have prepared their annual report. They ask for a group of farm buildings, which will relieve congestion in the institution buildings proper. These should cost about $50,000. The superintendent further states that next year a cold-storage plant, asylums for fifty men and fifty women during maniacal attacks, and a laboratory will be needed. There were, on September 30, 377 patients in the institution against 270 a year ago. The per capita weekly cost of maintenance was $4.31.

Violations of Law.—Ulderic St. Pierre of Fall River has been convicted for the third time of holding himself out to be a physician without being duly registered, and has been sentenced to pay a fine of $500 and to be imprisoned for five months.——George W. Bradley, North Adams, who, it is alleged, purported to be a physician without having registered, was fined $100, the minimum penalty. He took an appeal.——Henry D. Noel, a "suggestive therapeutist" of Fall River, charged with practicing medicine without being duly registered, was fined $125, and in default of bonds, was confined in jail.

Bequests to Hospitals.—Mrs. Mary Longfellow Greenleaf of Cambridge, in her will, bequeathed $5,000 to each of four hospitals.——By the will of Nancy E. Rust of Boston, $10,000 is left to the Addison Gilbert Hospital, Gloucester; $5,000 to the Perkins Institution and Massachusetts Asylum for the Blind, and the balance, about $15,000, is to be given to the Addison Gilbert Hospital in memory of Elias E. and Esther G. Davison.——Lucy Richmond Read of Boston, in her will, bequeathed $5,000 each to the convalescent home of the Children's Hospital, Wellesley; the Willard Hospital for Dipsomaniacs, Bedford; the Channing Home for Consumptive Women, Boston, and the Sharon Sanitarium.——Lamont G. Burnham, Boston, by his will devised $150,000 to the Boston City Hospital for a new building.——By the will of Mrs. F. L. Ames of Taunton $5,000 is given to establish a free bed in the Massachusetts General Hospital and a similar sum to endow a free bed in the Boston Home for Incurables.

MICHIGAN.

Personal.—Dr. William H. Haughey, Battle Creek, has been appointed local surgeon for the Michigan Central Railroad.——Dr. George Dock, Ann Arbor, is journeying through California.——Dr. Henry D. Thomason, major and surgeon, U. S. V., who has been stationed in the Philippines for two years, is on his way to the United States.

Faculty Changes at College.—Drs. Robert S. Linn, Detroit, and Vernon J. Hooper, South Lyon, have been appointed professors of tropical medicine at the Michigan College of Medicine and Surgery, Detroit; Dr. Peter M. Campbell will take the chair of electrotherapeutics; Dr. Heneage Gibbes that of internal medicine and pathology, and Dr. E. C. Watson will lecture on laryngology and rhinology.

Comparative Morbidity.—For December, 1902, compared with the preceding month, influenza, pneumonia, scarlet fever, erysipelas, smallpox, measles and dysentery were more prevalent; and diphtheria, intermittent fever, cholera morbus and puerperal fever were less prevalent. Compared with the average for December in the 10 years, 1892-1901, smallpox, measles

and whooping cough were more than usually prevalent: and consumption, intermittent fever, remittent fever, dysentery and puerperal fever less than usually prevalent.

Muzzle All Dogs.—At a meeting of the State Board of Health, January 9, Dr. Victor C. Vaughan, Ann Arbor, made a report of the special committee on the subject of hydrophobia, and offered the following preamble and resolution, which were adopted:

Inasmuch as hydrophobia is widely disseminated throughout the state, and many people are being bitten by rabid dogs,

Resolved, That the State Board of Health recommends that municipal and township authorities order the muzzling of all dogs at large, and make and publish regulations to that effect.

The Most Dangerous Communicable Diseases.—Meningitis was reported present in Michigan during December, 1902, at 10 places; whooping cough at 39 places; measles at 63 places; typhoid fever at 110 places; diphtheria at 113 places; smallpox at 126 places; scarlet fever at 177 places; and consumption at 239 places. Meningitis was reported present at 3 places more; whooping cough at 12 places more; measles at 15 places more; typhoid fever at 9 places less; diphtheria at 35 places more; smallpox at 85 places more; scarlet fever at 34 places more; and consumption at 1 place less, in December, 1902, than in the preceding month.

December Mortality.—There were 2,666 deaths in the state during December, an increase of 309 over the preceding month. The death rate rose from 11.7 to 12.8 per 1,000, being slightly higher than the rate for December, 1901. Important causes of death were as follows: Tuberculosis, 194; typhoid fever, 59; diphtheria, 68; scarlet fever, 16; measles, 11; whooping cough, 23; pneumonia, 291; meningitis, 26; influenza, 35; cancer, 122; accidents and violence, 173. As compared with the preceding month, an increase was shown in the deaths from tuberculosis, diphtheria, pneumonia, influenza and external causes, and a decrease in the number reported from typhoid fever and scarlet fever. There were 5 deaths returned from smallpox. One death was reported from hydrophobia in Saginaw.

NEW YORK.

Typhoid at Ithaca.—The epidemic of typhoid fever at Ithaca has attained serious proportions. The nurses at the City Hospital have been obliged to give up their rooms for patients. There are at least 200 cases in the city, and the number is rapidly increasing.

Personal.—Dr. George D. Whedon, Syracuse, while ill, fell and fractured his right leg below the knee.——Dr. Julius E. Haight, on leaving the Utica State Hospital for the Manhattan State Hospital, Central Islip, L. I., was presented with a handsome toilet set by the employes.——Dr. William A. Allen, secretary of the Flushing Hospital for many years, has resigned.

Deaths During 1902.—The annual report of the State Department of Health shows the number of deaths to be 124,160, or 5,000 less than in the previous year, making a death-rate of 17 per 1,000. The zymotic mortality was high, and deaths from typhoid and scarlet fever increased; those from smallpox remained stationary. There were 8,800 deaths from pneumonia, 5,500 from Bright's disease and 4,000 from influenza.

New York City.

Trachoma Department.—On Oct. 20, 1902, the health department opened, as a part of Gouverneur Hospital, a special department for the treatment of contagious eye diseases. Between that date and January 3,791 cases were treated, the majority of which were of trachoma.

Personal.—Dr. George T. Stewart, formerly superintendent of Bellevue Hospital, has been appointed superintendent of hospitals of the board of health. His duties will be executive. ——A fire at the residence of Dr. John H. French, January 28, did damage to the extent of $1,500.——Dr. John A. Irwin, on retiring from the presidency of the British Schools and Universities Club, was presented with a seven-quart loving cup.—— Dr. L. Rosenwasser, medical inspector, has been suspended by Commissioner Lederle for receiving a fee in the line of duty. ——Dr. Earle E. Woolworth, Brooklyn, fell from his wagon, January 21, fracturing his skull.——Dr. Jesse T. Duryea, former superintendent of Kings County Hospital, was presented with a bronze statuette by the attending staff, January 15.—— The board of education has appointed as director of physical training for the schools of Greater New York Dr. Luther Halsey Gulick, the inventor of basketball.——On February 4 the Society of Alumni of Bellevue Hospital held a dinner at Delmonico's, and presented to Dr. John W. S. Gouley a piece of silver in commemoration of the fiftieth anniversary of his connection with the hospital.

So-Called Specifics for Tuberculosis.—The committee on the prevention of tuberculosis of the Charity Organization Society of the City of New York has adopted the following preamble and resolution:

WHEREAS, It has come to the knowledge of the Committee on Tuberculosis of the Charity Organization Society that many so-called specific medicines and special methods of cure for tuberculosis have been and are being exploited and widely advertised, and

WHEREAS, The advertisements of some of these cures have made such reference to the Tuberculosis Committee of the Charity Organization Society, or to some of its members, as to create the inference that this committee, or its members, recommend or advocate the use of many such so-called specifics or special methods of cure for pulmonary tuberculosis, or consumption, and

WHEREAS, There is no specific medicine for this disease known, and the so-called cures and specifics and special methods of treatment widely advertised in the daily papers are in the opinion of the committee without special value, and do not at all justify the extravagant claims made for them, and serve chiefly to enrich the promotors at the expense of the poor and frequently ignorant or credulous consumptives, therefore,

Resolved, That a public announcement be made that it is the unanimous opinion of the members of this committee that there exists no specific medicine for the treatment of pulmonary tuberculosis, and that no cure can be expected from any kind of medicine or method except the regularly accepted treatment which relies mainly upon pure air and nourishing food.

PENNSYLVANIA.

Health Board Meeting.—Dr. Benjamin Lee, secretary of the State Board of Health, announces a meeting of city and borough health boards west of the Alleghenies in Pennsylvania, to be held February 12. The meeting is to consider measures to stop the spread of smallpox.

Warning.—We are in receipt of information from Allentown and Reading that an individual calling himself F. Whiting is endeavoring to collect money an account of THE JOURNAL, and of the American Medical Association. This person has no authority to make collections, and any information as to his present address will be appreciated by THE JOURNAL.

Philadelphia.

Typhoid Fever Cases and Deaths.—The health report for the week ended January 31 showed 325 new cases of typhoid fever. The new cases of this disease during January numbered 1,303, with 161 deaths. It is officially estimated that 4,000 cases of typhoid fever are now under treatment in the city.

The Coroner Was Busy.—January was an unusually busy month for the coroner. During the time 302 cases were investigated, an increase of 54 over the corresponding period of last year. There were 4 homicides and 14 suicides, and a large number of deaths from accidental asphyxiation and from falls.

Anti-Hospital Act Repealed.—The quick passage by the legislature of the Berkelbach bill, repealing the anti-hospital act, opens the way for the acceptance by Philadelphia of the proffered gift of $1,000,000 or more for the establishment of the Henry Phipps Tubercular Institute. The bill was the first one signed by Governor Pennypacker. The work of the institute will be begun within a few days in temporary quarters. There is some opposition by residents of the neighborhood to the location of the institution, but it is thought that this feeling will subside when the absence of danger of contagion is understood.

GENERAL.

Hawaiians protest against making their leper settlement a national leper colony.

The Mexican plague has extended to Guaymas and has also broken out in the soldiers' barracks at Mazatlan.

Gulf Quarantine Arranged.—Health officers representing Texas and Louisiana met at Galveston, Tex., January 26, and formed rules governing the shipping in the ports of those states.

Southern Pacific Hospital Cars.—This road will soon construct cars to be fully fitted out for medical and surgical aid and to be stationed on each division ready to be rushed to the scene of accidents when they occur.

Razlag's Leprosy Treatment.—Dr. Adolph Razlag is seeking a government to take up his plan of leprosy treatment which was mentioned in THE JOURNAL some time ago. He has sent a proposal to Washington by Consul McWade at Canton, China, near which city he is said to be curing lepers.

San Francisco Plague Report.—Dr. D. M. Currie gives, January 19, under direction of Surgeon A. H. Glennan, of the U. S. P. H. and M.-H. S., a review of the situation from which we note the following points: The Chinese object to autopsy,

and, having found that the sick who are examined and have a diagnosis of other disease established are not subjected to autopsy in case of death (as a rule), they report many cases of sickness in hopes of avoiding the autopsy which is held on bodies dead with suspicious signs or dead from indeterminable causes. They, however, can recognize typical bubonic plague and do not report such cases, knowing that autopsy is sure if the case is discovered. Some bodies, it is supposed, are removed from the city, but a spread of the disease is not probable from this cause, as observation has shown that few or no contacts contract plague. The report contains the following significant statement: "Except from the certificates of the attending physicians we have no means of ascertaining whether the whites in different parts of the city dying are infected with plague."

CANADA.

French-Canadians Banquet.—The French-Canadian members of the profession gathered in large numbers at the Place Viger Hotel, Montreal, on the evening of January 27, at the annual banquet of the Societe Medicale de Montreal. The event proved in every way most enjoyable.

Toronto's Health for January.—The number of contagious diseases reported in Toronto for January was as follows: Diphtheria, 57; scarlet fever, 105; typhoid fever, 12; smallpox, 5 cases, with 1 death. The medical health officer recommends an addition to the Isolation Hospital to be constructed at a cost of $30,000.

Vancouver Plague Quarantine.—Dr. McAlpine, medical health officer of Vancouver, B. C., received, January 22, a letter from the Board of Trade of San Francisco, stating that the plague is pretty well under control in that city, and that there have been no fresh cases since December 15. In view of this letter Dr. McAlpine does not think he would be justified in taking any immediate action with regard to the report of Dr. Fagan to the British Columbia government, and examine all passengers who arrive across the line in Vancouver.

Personal.—Dr. William Oldright, professor of hygiene in the medical department of the University of Toronto, with his son, Dr. H. H. Oldright, of St. Catherines, Ont., have returned from a trip to the West Indies, including Martinique.——Dr. W. W. Andrews, Mount Allison University, Sackville, N. B., has invented a microscope for dissecting purposes, which is said to be a very practical apparatus. Dr. George Hetherington, superintendent of the provincial lunatic asylum, N. B., entertained about thirty members of the St. John Medical Society at the institution one evening last week, when he delivered a general address on insanity.

FOREIGN.

King Edward has a mild attack of influenza.

French petroleum drinking is such an evil that measures are proposed to combat it.

Hydrophobia Germ.—Professor Sormagni of Milan is reported to have discovered the microbe of hydrophobia.

Thames Typhoid Scare.—The oyster source of typhoid in London has created a scare with regard to all edible products of the Thames river and threatens the business of the large population engaged in the fisheries.

Rejects Yellow-Fever-Mosquito Theory.—The Italian commission which has been studying yellow fever in Brazil reported February 3, at Rome, rejecting the theory of transmission by mosquitoes.

Weekly Edition of Archives de Medecine.—In entering on its eightieth year the Paris *Archives Gén. de Médecine* becomes a weekly instead of a monthly. It has included on its editorial staff such men as Claude Bernard, Trousseau, Duchenne de Boulogne, Velpeau and Broca. The present staff contains much young blood, and several new departments have been added.

Germans Report Value of Hypnotism.—The commission of experts in mental diseases, appointed by the German Ministry of Education a year ago to investigate the healing value of hypnotism, reports that it can be used in some instances to remove symptoms, but that it can not produce organic changes or cure epilepsy or hysteria. The report also remarks that hypnotism is less used than formerly. The commission consisted of Professor Mendel and Drs. Gock, Mentor and Aschenborn.

Formic Acid Vital to Organism.—Dr. Garrigue of Paris is reported in the lay press to have enunciated the theory that formic acid is a necessary product of the blood and that microbic invasions use it up and that formic acid is a valuable treatment in such cases, as it creates the oxygen that is essential to cell life. This is interesting in view of the fact that formic acid may be obtained from urine, sweat and blood and in view of the recently-reported successes with the injection of formalin solution in septicemia.

Matches Without Deadly Phosphorus.—A bill was proposed in the German reichstag, January 29, to prohibit the use of phosphorus in making matches on the ground that the government had acquired the patent of a new igniting substance harmless to the health of the employes and had placed it at the disposal of the match factories. In discussion, attention was called to the fact that France has a standing offer of $12,500 for the invention of a satisfactory substitute for phosphorus and the prize has not yet been awarded.

Diseases for Which Compulsory Notification is Advocated.—The Paris Académie de Médecine recently voted the following list of 14 diseases that should be invariably notified: Beside typhoid fever, exanthematous typhus, variola, varioloid and scarlet fever, measles, diphtheria, cholera and choleriform affections, plague, yellow fever and dysentery, it includes miliary fever, puerperal infections "when secrecy in regard to the pregnancy has not been enjoined," and also ophthalmia neonatorum under this same restriction. The list of diseases in which notification is optional includes 9: Pulmonary tuberculosis, whooping cough, la grippe, pneumonia and bronchopneumonia, erysipelas, mumps, leprosy, tinea, purulent conjunctivitis and granular ophthalmia. The list was drawn up at the request of the government. Laveran was anxious to have tuberculosis included in the first list and dysentery placed on the optional list, but was voted down. Brouardel stated that the public disinfection service is not prepared to undertake such a task as would be required if chronic tuberculosis were included in the compulsory class. The special committee had reported in favor of adding epidemic cerebrospinal meningitis and pneumonia to the first list, but were not heeded.

PARIS LETTER.

Hospital Reform in Paris.

Important reforms in the management of Paris hospitals are, it seems, about to be carried out. One of the most important is the suppression of the excessive centralization of all administrative measures, which prevented the hospitals from being relatively independent institutions such as those of London or New York. In Paris everything connected with any one of the hospitals must be reported to the central administration, which has its offices on Avenue Victoria, near the Hotel de Ville. The director of the hospital is a salaried employe, having no board of trustees to consult, and carrying out the wishes of the physicians in a more or less perfunctory manner. It will be sought to do away with all of this by giving each hospital its own autonomy, its annual budget. Each director will be able to show more initiative, and he will be counseled by a certain number of physicians and men known in the hospital quarter for their philanthropy and administrative ability. Such a reform would cause the French hospital to resemble more closely the English or American hospital.

Dr. H. de Rothschild's New Polyclinic.

A polyclinic was opened last month in one of the densely populated quarters of Paris. The money for its construction was furnished by Dr. H. de Rothschild, a member of the wealthy family bearing that name. The important specialties will each have a special section, such as ophthalmology, laryngology, orthopedic surgery, and radiography. Attached to the establishment is a large library of 10,000 volumes, chiefly concerning children's diseases. The inauguration ceremonies were carried out with some éclat, the minister of the interior, M. Chaumié, being present.

Bouchard and Robin at Variance.

At the Cairo Medical Congress, Dr. Bouchard made an important communication on the modern tendencies of therapeutics, and certified that general treatment was not apt to be so beneficial as local treatment. He described the results he had obtained by hypodermic injections of salicylic acid in rheumatic arthritis. Dr. Bouchard did not seem to wish to convey the impression that he was the inventor of this method, which is applied in many ways nowadays. In a recent number of the *Presse Médicale* Prof. Albert Robin

has published a letter in which he expresses his astonishment in seeing that Dr. Bouchard does not mention those who had previously carried out experiments on this very subject. He then quotes a passage from his work on "Diseases of the Stomach," p. 269, in which he refers to the use of drugs locally, and to the possibility of using small, minute doses in such cases. It yet remains to be seen how Professor Bouchard will accept this from Professor Robin, who is a younger man, and who has not the weight nor the universal reputation of the disciple of Charcot.

Lannelongue and Landouzy Decorated by the Emperor of Germany.

Professors Lannelongue and Landouzy, who attended the recent congress of tuberculosis held in Berlin, have been favored with the insignia of knights of the Royal Order of the Crown of Prussia.

Pasteur's Monument in Paris.

The site for Pasteur's monument has not yet been chosen definitely. It was to have been erected on the Place de Medecis opposite the Pantheon, then near the Sorbonne, lastly in the Avenue de Breteuil, opposite the dome of the Invalides. When work on the foundations was to be started it was found that the view of the Invalides might be interfered with on account of the height of the monument, so that the definite site remains an unsettled question.

Correspondence.

Dr. Croftan's Iodin Starch Test for Adrenal Extract.

CHICAGO, Jan. 29, 1903.

To the Editor:—Dr. S. P. Kramer, under the above caption (THE JOURNAL, Jan. 24, p. 257), mentions the fact that a series of organ extracts and ferment solutions other than adrenal or hypernephroma extract possess the power of decolorizing iodin starch solution. The inference is that this test is, therefore, of no value in the differentiation of adrenal tumors of the kidney from other tumors of this organ.

That the preparations enumerated by Dr. Kramer can decolorize iodin starch solution is known to me. The decolorization is, however, by no means so prompt nor so complete. I could supplement his list by a considerable number of other bodies with reducing properties that can do the same. The practical value of the hypernephroma test is not, however, impaired hereby. For, as I took pains to determine and as I expressly mentioned in my "Note," no other normal or abnormal constituent of the *kidneys* gives this test. It is hardly probable that the surgeon or pathologist will look for "Thyroid (P. D. & Co.), thymus (Armour), extract of meat (Liebig), pepsin (Fairchild), or pancreatic extract (Dry)" when attempting to identify a tumor of the kidney. None of these commercial products, moreover, give the other tests for adrenal tissue that I have described, with the exception of thyroid gland that may occasionally produce glycosuria, and pancreas that possesses diastatic powers.

I should advise Dr. Kramer to write me first hereafter before jumping into print with a criticism that is so misleading to the casual reader. ALFRED C. CROFTAN.

The Nobel Prizes, the Carnegie Institute, and the Promotion of Scientific Research.

CHICAGO, Jan. 26, 1903.

To the Editor:—The beneficiaries of the Nobel fund receive $40,000 as a reward for past achievement; the beneficiaries of the Carnegie fund, according to the last report of the "Institution," are to receive "not more than $1,000 a year" as an incentive to future achievement. The recipients of the Nobel prizes have arrived at the zenith of their scientific career and, presumably, do not need this stipend. The recipients of the Carnegie money are expected some day to climb to equal heights, presumably with the aid of a thousand dollars a year.

It is stated expressly that the men who are made beneficiaries of the Carnegie Institution must have shown "particular aptitude for the prosecution of original investigations," must be willing to devote all their time to advance research, and must agree to publish nothing without the approval of the Carnegie directors. In return they are to receive an emolument that approximately equals the salary of a policeman, a letter carrier or a street-car conductor.

It seems altogether improbable that any man who has really had an opportunity to show particular aptitude for original research will avail himself of this pittance under these conditions. It all depends on what we agree to understand by aptitude for original investigation. Much work passes for original research that is merely descriptive in character. The fact that a certain self-evident phenomenon has not been investigated and published heretofore may very well signify that no one has so far considered this particular fact or phenomenon worth investigating. Nine-tenths of the "research" that floods our journals consists of just such work, and constitutes in no way the solution of any problem that seems to urgently call for solution. The pathologist describes a tumor of the brain—this particular tumor, it is true, may never have been described before, but a thousand others like it have been described and redescribed; the physiologist measures the contractions of the unstriped muscles of the cat's bladder; the anatomist describes one of the thousand possible abnormalities in the course of the colon; the bacteriologist finds a new microbe in the shrimp, and bestows on it a long name, et cetera ad nauseam. This is not research. This is carrying the hod and carting bricks. True, some one must do this work, and it is well that some one should be doing it. The value of such investigations, however, is exactly on a par with the work of a corps of surveyors in a hitherto unsurveyed territory, or with the first reports of a gang of fire inspectors in regard to the architecture of this, that or the other of a thousand buildings. What we need are constructive geniuses, minds that can make this heterogenous conglomerate of disconnected facts the basis of some new conclusions; minds that, standing on such a fundament, can see far and beyond and can tell us what they see. Such men are rare; such men *have* shown a particular aptitude for research; such men receive the Nobel prizes, and such men are not for sale for $1,000 a year.

Even those young workers who, under the direction of a competent teacher of technic and a prolific purveyor of "ideas" and "problems," are willing to comply with the rules of the Carnegie Institution are ultimately damaged in their career. Assuming them, *exempli causa*, to be medical men, then three fields of activity stand open—practice, teaching, research. No one man can very well achieve great things in all three fields; it is quite feasible, however, for a man to practice or to teach and still find time to do creditable research work besides. It must be a poor practitioner and a poor teacher indeed who cannot command $1,000 a year by the time he is "particularly apt." Twenty laboratories are open to a man with such ambitions in this country, and fifty more abroad, where he will be received with open arms. While carrying on his research he is building up his practice or establishing his reputation as a teacher. The victim of the Carnegie munificence, as administered by the Carnegie directors, can do neither—he simply researches—and in so doing he gambles with his time; for unless he is investigating some phenomenon that is so patent that he *must* get some results—and such phenomena are manifestly not worth investigating at a sacrifice—he may find at the expiration of a year or of two years that the results of his investigation are *nil* or negative, for the reason that his or his chief's working hypothesis was wrong; this happens a thousand times in all laboratories. One might as well say to a promising young man with a philosophic bent of intellect: "Here, young man, is $1,000. This will enable you to eat for a year. Now show your particular aptitude for philosophy; philosophize for the term of your fellowship (subject to the approval of the Carnegie directors) and become an Emerson." Or, "Here, young friend, you have occasionally broken out into poetry; take this thousand, agree to do nothing else but follow your Muse, and become a Longfellow, to the glory of the Carnegie Institution." We do not think that an Emerson, a Longfellow, a Newton, nor a Lavoisier has ever been lost to this world for the lack of a thousand a year. A true

investigator can not be repressed, nor can he be created by relieving him, in a fashion, at the outset of his career of the most acute responsibilities incident to keeping his body and soul together.

What the Carnegie Institution promises to furnish by its research fellowships are technical assistants to a few men in this country who are already at the head of well-equipped laboratories and who, if they have any inspiration in their own souls, should be, and are, surrounded by a corps of inspired and enthusiastic volunteer workers. The stipend of "not more than $1,000" will attract few constructive geniuses to such positions.

What we need, apparently, is a Mæcenas of Science who will not bestow a fortune on the successful worker when he is resting on his laurels and when he no longer needs support; and who will not offer a pittance so miserable that it is barely sufficient to keep body and soul together to the struggling youth—with possibilities—who is reaching for his laurels; but who will endow the investigator in the full vigor of his working manhood, and after he has had an opportunity to show his contemporaries that he is really "particularly adapted to prosecute original investigation," with a sum of money sufficiently large to enable him to live decently and comfortably and thus to carry out unhindered by financial worries the work that he may reasonably be expected to accomplish for the good of humanity. ALFRED C. CROFTAN.

Queries and Minor Notes.

ANONYMOUS COMMUNICATIONS will not be noticed. Queries for this column must be accompanied by the writer's name and address, but the request of the writer not to publish his name will be faithfully observed.

FORMALIN INJECTIONS FOR SEPTICEMIA.

LISBON, IOWA, Jan. 30, 1903.

To the Editor:—On page 253, January 24, in "Formalin Injections for Septicemia," do you state the proportions correctly? If not, will it not be the means of causing deaths in patients of physicians who rely on it being correct? I have used formalin in a case where I was called as consultant in puerperal septicemia and the patient seems to be slowly convalescing. I used 500 c.c. of a 1 to 5,000 solution of formalin—in median basilic vein of one arm one day and the same amount in same vein of the other arm the next day. E. BURD.

ANS.—On consulting our correspondent, we find that the strength should have been stated as 1 to 5,000. A case is reported in which the use of a 1 to 2,500 solution caused collapse, but McGuire (*London Lancet*, Dec. 1, 1900) used a strength of 1 to 800 on himself without serious results. This illustrates the uncertainty of the effects of these injections and emphasizes the necessity of extreme care. Especial attention is called to the Editorial in this issue.

PRACTICE IN ARIZONA AND NEW MEXICO.

MINNEAPOLIS, Jan. 26, 1903.

To the Editor:—Will you kindly inform me through your columns of the requirements for practice of medicine in Arizona and New Mexico? To whom can I write for further information? S. E. S.

ANS.—The medical practice law of Arizona requires the passage of an examination by the board and an approved diploma. The present status of the law is a little uncertain as it has very recently been declared unconstitutional by a local court. Whether the case will be carried higher, we can not say. In New Mexico all but the graduates of eight medical colleges will have to pass an examination. The institutions whose diplomas exempt from examination are the following universities: Pennsylvania, Harvard, Johns Hopkins, Columbia of New York, Missouri, Yale, Michigan and Minnesota. Dr. W. G. Hope, Albuquerque, N. M., is the Secretary of the New Mexico Board of Health, and Dr. Wm. Duffield, Phœnix, Ariz., is the Secretary of the Arizona Board of Medical Examiners.

THE PHYSICIAN AND THE PHARMACOPEIA—METHOD OF REDUCING STRENGTH OF SOLUTIONS.

DES MOINES, IOWA, Jan. 30, 1903.

To the Editor:—Another example of how ignorant competent physicians are of the U. S. Pharmacopeia is evident in Dr. Hardcastle's statement published in your issue of January 24. The Doctor's "Method of Reducing Strength of Solutions" is the one explained, adopted, and used by the U. S. P. This is the official rule for making all dilutions. (See U. S. P. on acids, alcohol, etc.) ELI GRIMES.

COW-POX SERUM INJECTIONS.

Jan. 28, 1903.

To the Editor:—Has the serum of a cow suffering from vaccinia ever been injected into a patient afflicted with smallpox; if so, with what result? I have never read of any such experiments in my limited supply of literature. H. L. F.

ANS.—We have not seen any record of such experiments. Would not this be an interesting field for investigation?

TRAINED MALE NURSES.

736 HUDSON AVE., ST. PAUL, MINN., Jan. 29, 1903.

To the Editor:—I am interested in becoming a trained nurse, but do not know what to do or where to go. Can you kindly inform me? Is the male nurse in demand? I would like some Eastern school if I could. FRANK KODA.

CASE OF CONGENITAL MEASLES.

BENTLEY, ILL., Jan. 26, 1903.

To the Editor:—I wish to report the birth of a child Jan. 23, 1903, with the measles in eruption. The mother's eruption began Jan. 16, 1903, after tardy prodrome. Both doing well.

Very Truly, F. S. AGLER, M.D.

WANTS A SEQUARIAN LAMP.

LINTON, IND., Jan. 24, 1903.

To the Editor:—Where can I obtain a Sequarian lamp?

M. N. THAYER.

Marriages.

JOHN H. RINDLAUB, M.D., to Miss Marie Douglas, both of Fargo, N. D., January 31.

LOUIS A. GAUDIN, M.D., Convent, La., to Miss Louise Ilsley of New Orleans, January 21.

FRED SCRIVER SPEARMAN, M.D., to Miss Olive L. Pooler, both of Hawkeye, Iowa, Nov. 7, 1902.

J. ABNER PENTON, M.D., Goodwater, Ala., to Miss Mildred Parker of Equality, Ala., January 27.

LUTHER HAYS, M.D., Cullman, Ala., to Miss Ethel Olivia Watson of Vinemont, Ala., January 20.

JOHN DOUGLAS, M.D., Florence, Ala., to Miss Marguerite Pearl Burford of Birmingham, January 28.

CHARLES DICKENS WILLIAMS, M.D., Cleveland, Ohio, to Miss Annie Martin of Lisbon, Ohio, January 28.

JOHN L. WORCESTER, M.D., Birmingham, Ala., to Miss Elizabeth Blakeslee of Kansas City, January 28.

WILLIAM C. BLOOMER, M.D., Cleveland, Ohio, to Maud McConoughey of Chagrin Falls, Ohio, January 19.

EDGAR K. WARD, M.D., Park City, Utah, to Miss Myrtle Hale of San Francisco, at Salt Lake City, January 15.

T. A. JONES, M.D., Springfield, S. C., to Miss Annie E. Sawyer of Sawyerdale, S. C., at Perry, S. C., Dec. 17, 1902.

WILLIAM O. POWELL, M.D., Mackinaw, Ill., to Mrs. M. Louise Coney of Bloomington, Ill., in Chicago, January 21.

PEDER S. BRUGUIERE, M.D., San Francisco, to Miss Maryan Andrews of Pine Knoll, Cal., at Reno, Nev., Dec. 21, 1902.

JOHN W. BRAMLETT, M.D., Campobello, S.C., to Miss Eva Wilkes of Chester, S. C., at Spartanburg, S. C., January 26.

I. R. SHUMAN, M.D., Wagon Mound, N. M., to Miss Elizabeth C. Gotwats of Norristown, Pa., at Santa Fe, N. M., Oct. 4, 1902.

Deaths.

Eugene Foster, M.D. Medical College of Augusta (Ga.), 1872, a member of the American Medical Association; professor of practice of medicine and sanitary science and dean of the faculty of the medical department of the University of Georgia; president of the Georgia Medical Society in 1885; president of the Richmond County Medical Association in 1890; member of the New York Medicolegal Society; member of the American Public Health Association; member of the American Surgical Association; president of the board of trustees of the Georgia State Sanitarium; president of the Augusta Board of Health for twenty-five years, and one of the most prominent and highly-esteemed physicians of the state, died at his home in Augusta, January 23, after an illness of three months, from

cancer of the stomach, aged 53. He was an acknowledged authority on municipal sanitation, and his contributions to medical literature are numerous and valuable. The student body of the medical department passed suitable resolutions regarding the death of Dr. Foster.

Harrison Augustus Lemen, M.D. St. Louis Medical College, 1864, some-time president of the Denver Medical Society and of the Colorado State Medical Society; emeritus professor of principles and practice of medicine in the medical department of the University of Denver, and for many years a member of the State Board of Health, died at his home in Denver, January 21, after a long illness from kidney disease, aged 62. He retired from practice in 1893.

Margaret Stanton, M.D. College of Medicine, Syracuse University, 1876, formerly president of the Onondaga County Medical Society, died at her home in Syracuse, January 22, from tuberculosis, after an illness of several years, aged 58. At a special meeting of the Onondaga County Medical Society resolutions were passed lamenting the death of Dr. Stanton, offering a tribute to her memory and extending sympathy to her family.

Patrick H. Conley, M.D. Rush Medical College, Chicago, 1887, a member of the attending staff of Cook County Hospital, surgeon to the West Side Hospital and professor of obstetrics and diseases of children at the Chicago Clinical School, died, February 3, at Mercy Hospital, Chicago, after an operation for appendicitis, aged 43.

Eugene Davis, M.D. Medical College of Indiana, Indianapolis, 1893, a member of the American Medical Association and professor of ophthalmology at the Medical College of Indiana, died at his home in Indianapolis, January 19, from typhoid fever, after a short illness, aged 30.

Christopher Kiersted, M.D. Albany Medical College, 1846, a lineal descendant of Hans Kiersted, the first surgeon to settle in New Amsterdam, died from gastritis at his home in Jersey City, N. J., January 23, after an illness of several days, aged 81.

Joseph Edwin Clark, M.D. College of Physicians and Surgeons, New York, 1849, for many years president of the medical board of St. Peter's Hospital, Brooklyn, died in that institution, January 19, from pneumonia, aged 79.

Cyrus Allen, M.D. New York Homeopathic College and Hospital, 1864; Berkshire Medical College, Pittsfield, Mass., 1865, died from heart disease, January 14, after an illness of one year, at his home in Avon, N. Y., aged 65.

David C. Pusey, M.D. University of Louisville, Ky., 1853, president of the Meade County Medical Society and chairman of the board of health, died at his home in Brandenburg, Ky., January 20, after an illness of a year.

R. Otway Owen, M.D. Medical College of Virginia, Richmond, 1889, of Kansas City, Mo., died at San Bernardino, Cal., January 19, from concussion of the brain due to a runaway accident, six days before, aged 38.

E. Edwin Spencer, M.D. Eclectic Medical Institute, Cincinnati, 1860, chairman of the Cambridge (Mass.) Board of Health, died suddenly at his home in Cambridge, January 19, from heart disease, aged 69.

Charles W. Vimont, M.D. University of Louisville, 1889, died suddenly at his home in Chicago, February 1, from angina pectoris, while apparently convalescent from an attack of typhoid fever, aged 37.

Adam T. Van Vranken, M.D. Albany Medical College, 1873, a member of the New York State Medical Association, died at his home in Watervliet, N. Y., January 19, from paralysis, aged 55.

Joseph M. Donaldson, M.D. St. Louis Medical College, 1876, of Kansas City, Mo., died at Excelsior Springs, Mo., January 22, from nephritis, after an illness of several months, aged 53.

C. Everett Watson, M.D. Cleveland Homeopathic Medical College, 1898, of Conneaut, Ohio, died at Phœnix, Ariz., January 18, from laryngeal tuberculosis, after an illness of two years, aged 27.

Margaret Taylor Shutt, M.D. Cornell University, New York, 1899, a member of the American Medical Association, died at her home in Springfield, Ill., January 24, from typhoid fever.

John J. Manion, M.D. Rush Medical College, Chicago, 1895, died at his home in Charlotte, Iowa, January 24, from typhoid fever, after an illness of three weeks, aged 25.

Alpheus Dove, M.D. Eclectic Medical Institute, Cincinnati, 1854, died from paralysis at his home in Brookville, Ohio, aged 74.

Association News.

NEW ORLEANS COMMITTEE OF ARRANGEMENTS.

Meeting held in the rooms of the Orleans Parish Medical Society, New Orleans, Jan. 26, 1903.

[*Abstract from the New Orleans Med. and Surg. Jour. of February.*]

There were present with the Committee of Arrangements Drs. Frank Billings and George H. Simmons, President and Secretary of the American Medical Association.

Reports on Finance, New Membership and Entertainment.

DR. CALLAN, chairman of the Finance Committee, reported that subscriptions had been received aggregating $2,910 from physicians and $435 unsolicited from laymen. Of the physicians in the city but 2 had refused to contribute, 47 had not been seen, 18 were to answer later, and 197 had contributed sums ranging from $5 to $100; $259 in cash has already been collected. The subscriptions are due March 1, 1903. The committee is still continuing the work, and intends soliciting subscriptions from the physicians of Louisiana.

DR. F. W. PARHAM, chairman of the Committee on New Membership, said that 6,376 circulars had been sent out to members of state societies in Alabama, Louisiana, Mississippi, Florida, Arkansas and Texas and that Tennessee, Georgia and the Carolinas would be covered.

DR. L. G. LEBEUF, chairman of the Committee on Entertainment, reported progress as follows: Mrs. Maurice Stern had offered the use of her home and spacious grounds. Dr. Bloom had offered to take the Surgical Section or any fifty members of the association on a yachting party to the Tchefuncta river. The committee would arrange a river excursion on the Chalmette or some other big excursion steamer. An evening tea for the ladies would be held in the St. Charles Hotel palm garden. He mentioned some citizens who would probably extend the use of their homes and grounds for entertainments. In addition, several individual physicians had agreed to entertain at small dinings.

Meeting Places.

DR. JOHN F. OECHSNER, chairman of the Committee on Halls and Meeting Places, then submitted his report. It had been the intention of the committee to use Tulane Hall as a center, but in accompanying Drs. Billings and Simmons during the afternoon in a short visit to the various halls in view, he had come to the conclusion, after a conference with these gentlemen, that another arrangement would be better. Drs. Billings and Simmons were of the opinion that Washington Artillery Hall offered an ideal place for the location of the exhibit hall and one of the large sections. Another smaller hall in the same building was available. The comparison of floor space showed that in Washington Artillery Hall there would be an available area for exhibits of 11,000 square feet, as against 3,966 square feet available for this purpose in Tulane Hall.

The discussion of available halls in proximity to Washington Artillery Hall then followed. DR. FRIEDRICHS moved that Washington Artillery Hall be selected as a center. DR. PARHAM asked for Dr. Simmons' opinion. DR. MATAS requested Dr. Simmons' opinion as to disposition of various sections.

DR. SIMMONS had only seen the Council Chamber, Washington Artillery Hall and Odd Fellows' Hall. The exhibit hall he considered the most important factor under consideration. The registration bureau and postoffice should be central and in immediate proximity to the exhibit hall. He considered Washington Artillery Hall ideal for the purpose. The main hall would be ample for the exhibitors, registration and information bureaus and postoffice. He had seen Tulane Hall, and considers it not half large enough for the purpose. The various halls in Tulane Medical College and in the Polyclinic he advised the committee not to consider. He believed

that the amphitheater was not at all suitable for meetings of medical associations; while it offers an opportunity for the man reading the paper to be heard, the arrangement is not such as to be favorable for the discussion, which is often the most important part of the proceedings. He had seen Odd Fellows' Hall and considered it somewhat objectionable, because of the noise on Camp street. Quiet is an important factor. The Washington Artillery Hall, with its 11,000 square feet, he believed too large for any section, and suggested the use of canvas partitions. If a room is too large it will encourage the presence of idlers in the rear, who, not being themselves able to hear, talk and disturb the proceedings.

It was suggested that it would be advisable to put sections on medicine and surgery as near as possible. All sections wished to be near these two sections.

As a substitute to Dr. Friedrichs' motion, DR. DE ROALDES moved that the selection of the central meeting place be left to the discretion of the Committee on Halls and Meeting Places. He believed that immediate action would be premature.

DR. MATAS considered it advisable to bring up the question and decide it at once. The Committee on Exhibits had already planned to utilize Tulane Hall, and if a change were to be made it must be enabled to go to work at once to revise plans.

DR. KOHNKE suggested hearing the report of the Committee on Exhibits. At the request of the chair, Dr. Friedrichs withdrew his motion, and Dr. Kohnke, chairman of the Committee on Exhibits, then delivered his report.

The committee, believing that the selection of Tulane Hall was final, had drawn up diagrams of the space available for exhibits. There was a total of actual space, including the galleries, of 3,966 square feet, which would yield a total rental of $6,330, the prices for these spaces varying from $150 to $40. In closing, Dr. Kohnke urged on the committee the necessity for immediate action with regard to exhibit hall.

DR. BILLINGS said that in arranging for the meeting of a large body of medical men there are two most important considerations: First, comfortable meeting places, which should be easy of access. Second, sufficient hotel or other boarding accommodations. He believed Tulane Hall unsuitable for the exhibit hall; it would be absolutely impossible to get exhibitors to take space in the gallery. The smaller room in this building is not desirable. He considered the college amphitheater as a most undesirable meeting place—although for a medical body, still the atmosphere of medical colleges is not pleasing. As to the Tulane Medical College, he believed that the amphitheater on the third floor could not be used because of the number of stairs to climb to it. Washington Artillery Hall he considered an ideal place. He made the suggestion that a restaurant could be run, which would furnish a source of revenue. He did not approve of free lunches. It had always been a problem at previous meetings of the Association to secure an adequate midday meal during the noon hour. Churches had heretofore been the most satisfactory meeting places. Distance is not an objection, provided places of meeting are on a car line and within a few minutes' ride from hotel headquarters.

DR. FRIEDRICHS made his motion to read that the committee select Washington Artillery Hall as a location for the exhibit hall, bureaus of registration and information and postoffice, provided same can be secured. The motion carried.

DR. BILLINGS suggested that the Committee on Exhibits make a diagram of their hall, set a price on the whole, and divide it up as they saw fit.

Badges.

In the absence of DR. GESSNER, chairman of the Committee on Badges, DR. WALKER submitted the committee's report. The committee believed that 5,000 badges would be necessary, distributed as follows: Members, 3,000; guests, 1,500; exhibitors, 500; delegates, 150; sections, 24; committees, 50.

In discussing, DR. SIMMONS mentioned the fact that the badges for delegates were furnished by the Association. He advised against expensive badges, and did not consider guests' badges necessary. However, not over 50 might be provided for invited guests; 1,000 badges for ladies and 500 for exhibitors would be ample. He considered a ribbon most suitable. It should be demanded of every one that he or she show a badge of some sort before being admitted to the exhibit hall. Heretofore the exhibit hall had been open to the public, and such was objectionable both to the profession and to exhibitors.

DR. WALKER showed a design for a badge which the committee had selected. The cost, $175, with satin ribbons at $43, would aggregate $218. If finer ribbed silk ribbons were used it would bring the total expenditure up to $335. Various suggestions as to designs were made.

DR. OECHSNER considered that the committee should see to it that the badges should be worth preserving, and was of the opinion that the committee should not limit itself to $350 for this purpose.

Banquets.

DR. DE ROALDES, chair of the Committee on Banquets, asked for information from Dr. Simmons as to banquets of various sections.

DR. SIMMONS said the sections on surgery and gynecology sometimes combine in a banquet. The section on practice of medicine usually has a banquet, and the sections on laryngology and ophthalmology usually combine. He would suggest writing to the various chairmen of sections not later than February 15 for information with regard to the wishes of their sections in this respect. Each section pays its own banqueting expenses.

THE CHAIR stated that communications had already been sent out to the various chairmen in this regard. From one of the chairmen of sections came the suggestion that smokers would be more desirable in every respect than a formal banquet.

DR. BILLINGS said the arrangements for banquets were usually partially made on account of neglect of the members of the sections to signify their wishes. He believed the idea of general smokers to be a good one, that is, to have on the first night of the meeting—the only night of the meeting which is available—two or three smokers for the general membership.

Information Bureau.

DR. FRIEDRICHS, chairman of the Bureau of Information, reported as follows: This committee has held several meetings and has adopted the following plan to carry out its work: An apartment will be selected at the place of the general meeting. The committee recommends an arrangement with the Committee on Registration to have a place in common, where the work of the two committees can be more efficiently carried out. This room will be fitted up with telephone and connected with the messenger service. A sub-committee is collecting all needed information about the city and state for use of visitors.

From the present outlook I feel confident that this committee will have everything in readiness at least a month in advance of the time of the meeting.

Publicity.

DR. FELIX A. LARUE, chairman of the Program and Publication Committee, said: I beg to state that we have had very little to do. The *New Orleans Medical and Surgical Journal* has, from time to time, contained news of general information, which was sent to THE JOURNAL of the American Medical Association and other journals throughout the country.

Registration.

DR. R. MATAS, for the Committee on Registration, reported that instructions as to his bureau had been received from the treasurer, and the details would be carried out when a definite location had been assigned.

Hotels.

DR. MOSS, representing Dr. Martin of the Committee on Hotels, reported that he knew nothing of anything done since the last meeting of the Committee of Arrangements, November 15, except the negotiation with Ingram's Boarding House Agency, who would agree to take charge of the meeting for the sum of $200, to be paid by the committee. Or this agency would take the matter in charge for $100, provided they were allowed the privilege of issuing tickets to each applicant for a location, these tickets to be paid for by the applicant, to

cost $1.00, the price of which would be remitted on the board bill of applicant. This last arrangement did not meet with the approval of the committee.

DR. SIMMONS considered the work of this committee as of the highest importance. He considered that the attendance at the meeting would be about 4,000. Heretofore considerable overcrowding had been experienced in hotels. He would suggest that the Association would not be long in coming again if its meeting were well managed this time. He believed that private boarding houses are far better than crowding members into hotels. He cited the instance of the British Medical Association, at which meeting nearly all of the visitors were accommodated in private families, not really boarding houses. As to hotels, Dr. Simmons urged the necessity of getting from each proprietor prices for rooms, with bath, without bath, for one, two, three or four in a room; these rates to be given in writing and published in advance. Some hotel keepers do not care to furnish this information in writing. However, they can be given to understand that unless these conditions are complied with no notice will be made of these establishments in the advertising matter sent out.

Citizen's Auxiliary Committee.

MR. CHARLES FARWELL, chairman of the Citizens' Auxiliary Committee, reported that he had secured a number of ladies who had consented to act on the ladies' reception committee, of which Mrs. Samuel Delgado was chairman.

Medical Organization.

Conference on Organization.

A conference on organization by representatives of the state societies of Louisiana, Alabama, Arkansas, Florida and Mississippi was held at the Orleans Parish Medical Society rooms, New Orleans, January 27. Among those present were Drs. W. E. B. Davis, Alabama; J. P. Runyan, secretary of the Arkansas State Medical Society; J. H. Pierpont, president of the Florida State Medical Society; S. C. Red and H. A. West, president and secretary of the Texas State Medical Society; H. W. Folkes, J. F. Hunter, Mississippi; Isadore Dyer and W. M. Perkins, president and secretary of the Louisiana Medical Society; Dr. W. W. Hall, Aquilla, Miss.; some fifteen others interested in organization, and the president and secretary of the American Medical Association.

DR. FRANK BILLINGS acted as chairman and spoke first, calling attention to the reasons for such a conference and to the value to be derived from an organized profession, reviewing the work already accomplished. The difficulties already surmounted were referred to, and those yet to be overcome were outlined.

DR. SIMMONS called attention to the necessity of organization if the profession is to have any influence, and especially to its value to those who are isolated. He told of the new relationship of the National Association to the state society and the responsibility of the latter in creating the legislative body of the American Medical Association. It will not be long before it will be realized that one of the highest honors a state society can confer on a member will be to elect him to represent the state in the House of Delegates of the American Medical Association.

DR. W. E. B. DAVIS reviewed the history of the Alabama State Association, stating that the scheme now adopted by the American Medical Association for state societies originated in Alabama thirty years ago, and has proved wonderfully successful in spite of the fact that it had none of the advantage that will be had through coöperation when all the states are organized in like manner. He spoke of the fact that they have a record of every man licensed to practice in the state, know exactly how many there are, and where they live.

DR. RUNYAN of Arkansas stated that his state society had adopted the constitution recommended by the American Medical Association and described how well it is working. Heretofore there were no county societies, and at the last meeting the state society had less than 300 members. It has already increased to nearly 800. There are ten councilor districts, and the councilors are actively at work. For the present the per capita tax for state dues is $2.00, which is paid by the county societies.

DR. PIERPONT of Florida said that his state was poorly organized, the state society having less than 175 members. They hope to adopt the American Medical Association constitution for state societies at the next meeting.

DR. RED of Texas spoke of the serious difficulties which confront them in that state. The size of the state is one, and the fact that some of the large district societies are opposing the movement is the other. He thought, however, that the plan recommended would be adopted, modified by dividing the state into 17 districts, and have the county form the district and the districts form the state society.

DR. WEST also spoke of the difficulties in Texas, but thought that his state would come out all right next April and would be in line.

DR. HUNTER of Mississippi said that a committee on reorganization had been appointed and would report favorably on the adoption of the recommended constitution.

DR. DYER said that Louisiana will be in line next April, and that the committee had already printed the constitution adopted by the American Medical Association. Louisiana has already adopted the card index system for keeping a record of those licensed to practice in the state, and it is now about complete.

A general discussion then took place, nearly all present taking part. All were enthusiastic in believing that the plan now being adopted would result in an organized profession, such as was never thought possible heretofore.

Valley County (Neb.) Medical Society.

This society met at Ord, January 14, for organization and adopted the constitution and by-laws suggested by the American Medical Association. The officers elected were: Dr. Frederick D. Halderman, Ord, president; Dr. Chester A. Brink, Ord, vice-president, and Dr. D. S. Hogan, North Loup, secretary-treasurer.

Midland County (Mich.) Medical Society.

Dr. Harry B. Landon, Bay City, state councilor, organized this society at Midland, January 14. The following officers were elected: President, Dr. Abram D. Salisbury, Midland; vice-president, Dr. H. Watson, Edenville; secretary, Dr. William H. Brock, Midland, and treasurer, Dr. J. Henry Johnson, Midland.

Greene County (Tenn.) Medical Society.

The physicians of Greene County met in Greeneville, January 5, and organized this society with an initial membership of 17, and the following officers: Dr. John C. Marshall, Chuckey City, president; Dr. Eliot B. Smith, Greeneville, vice-president; and Dr. S. Walter Woodyard, Greeneville, secretary. The society will affiliate with the Medical Association of the State of Tennessee.

Summit County (Ohio) Medical Society.

In our issue of Nov. 1, 1902, the meeting of this society for reorganization on the lines proposed by the American Medical Association was noted; at the annual meeting in December the reorganization was effected, and on January 6 the following officers were elected: President, Dr. John H. Seiler; vice-president, Dr. Wellington W. Leonard; secretary, Dr. Edward W. Barton, and treasurer, Dr. Charles E. Norris, all of Akron.

Obion County (Tenn.) Medical Society.

Dr. Isaac A. McSwain, Paris, councilor for the district, organized the Obion County Medical Society, at Union City, Dec. 8, 1902, with 30 members. Dr. McSwain explained the need for organization and the plan proposed by the American Medical Association, after which permanent organization was effected, with the following officers: President, Dr. E. H. White, Rives; vice-presidents, Drs. P. N. Matlock, Mason Hall and J. M. Rippy, and secretary and treasurer, Dr. F. W. Watson, Union City.

Lorain County (Ohio) Medical Society.

This society met at Lorain, January 20, under the direction of Dr. Thomas C. Martin, Cleveland, councilor for the Fifth District and reorganized under the provisions of the new constitution suggested by the American Medical Association for county societies. The following officers were elected: Dr. Olney B. Monosmith, Lorain, president; Dr. Orlando T. Maynard, Elyria, vice-president; Dr. Clarence B. Wean, Lorain, secretary; Drs. Charles H. Cushing, Elyria, William C. Bunce, Oberlin, and Abraham N. Garver, Lorain, censors, and Dr. Ewan Cameron, Lorain, delegate to the state society.

Boyd County (Ky.) Medical Society.

The physicians of Boyd County, Ky., met at Ashland, January 16, to consider the question of organization. After adopting the constitution and by-laws framed by the American Medical Association the following officers were elected: President, Dr. Thomas R. Young, Ashland; vice-president, Dr. James W. Kincaid, Catlettsburg, secretary; Dr. Porter C. Layne, Ashland; treasurer, Dr. Alexander T. Henderson, Ashland; censors, Drs. John D. Williams, Catlettsburg, John D. Mutters, Rush, and J. Letton Martin, Ashland. There are 36 physicians in the county, and it is expected that every one will be enrolled in the society.

St. Joseph County (Mich.) Medical Society.

Pursuant to call of Dr. George W. Lowry, Hastings, councilor of the Michigan State Medical Society, fifteen physicians of the county met at Sturgis, Dec. 2, 1902, and organized a county medical society on the lines suggested by the American Medical Association. The annual meeting was held at Three Rivers, January 7, at which 7 new members were enrolled, and the following officers elected: President, Dr. Marden Sabin, Centreville; vice-president, Dr. Frederick W. Robinson, Sturgis; secretary, Dr. John R. Williams, White Pigeon; treasurer, Dr. Edward P. Partlow, Constantine; directors, Drs. Lawrence D. Knowles, Three Rivers, David V. Runyan, Sturgis, and Leal K. Slate, Constantine; committee on public health and laws, Drs. John H. Moe, Sturgis; Charles B. Long, Mendon, and Emory J. Brady, Constantine, and delegate to the Michigan State Medical Society, Dr. Lawrence D. Knowles, Three Rivers.

Kenton-Campbell County (Ky.) Medical Society.

The physicians of Kenton and Campbell counties met at Dayton, January 15, and organized this society, after an address by Dr. J. N. McCormack. The constitution and by-laws prepared by the American Medical Association were adopted, and the following officers elected: President, Dr. Charles B. Schoolfield, Dayton; vice-president, Dr. B. F. Laird, Covington; secretary, Dr. Frederick A. Stine, Newport; treasurer, Dr. Charles S. Helman, Ludlow; censors, Drs. Robert H. Thornton, Newport, William W. Tarvin, Covington, and August Helmbold, Newport. About sixty physicians were in attendance, and much interest and enthusiasm were manifested. As Covington, Newport, Dayton and Bellevue really compose one continuous city, although divided by a county line, it was thought best to organize the profession into one society, although this was a departure from the strict letter of the plan of organization.

Societies.

New York Academy of Medicine.—Dr. Louis J. Ladinski has been elected chairman, and Dr. Charles F. Adams, secretary, of the Section on Obstetrics and Gynecology.

Philadelphia College of Physicians.—This organization held its annual meeting January 7, at which Dr. Horatio C. Wood was elected president; Dr. Arthur V. Meigs, vice-president; Dr. Thomas R. Neilson, secretary, and Dr. Richard R. Harte, treasurer.

North Kentucky Medical Association.—This association convened at Erlanger, Dec. 11, 1902, and elected Dr. Charles W. McCollum, Erlanger, president; Dr. W. A. Scroggin, Dry Ridge, vice-president, and Dr. Myrix J. Crouch, Union, secretary and treasurer.

Rock County (Wis.) Medical Society.—At the annual meeting of this society Dr. William H. Palmer was elected president; Dr. Michael A. Cunningham, vice-president; Dr. George W. Fifield, secretary, and Dr. Frank B. Farnsworth, treasurer, all of Janesville.

Tipton County (Tenn.) Medical Society.—The annual meeting of this society was held in Covington, January 6, at which Dr. L. A. Yarbrough, Covington, was elected president; Dr. O. M. Walker, Munford, vice-president, and Dr. B. Vernon Dickson, Covington, secretary.

Winnipeg (Manitoba) Medical Association.—At the annual meeting of this body, Dec. 5, 1902, Dr. James W. Good was elected president; Dr. J. A. MacArthur, first vice-president; Dr. William J. Neilson, M.P.P., second vice-president, and Dr. Gordon Bell, secretary-treasurer.

Mahaska County (Iowa) Medical Society.—This society has been reorganized at Oskaloosa with the following officers: Dr. Joseph T. Coveny, president; Dr. Joseph C. Barringer, vice-president; Dr. Herman C. Homer, secretary, and Dr. Samuel W. Clark, treasurer, all of Oskaloosa.

Union County (Ky.) Medical Society.—At the annual meeting of this society in Morganfield, Dec. 1, 1902, Dr. William A. Richards, Morganfield, was elected president; Dr. T. E. Newman, Waverly, vice-president, and Dr. Roland H. Rhea, Jr., Morganfield, secretary and treasurer.

Wapello County (Iowa) Medical Society.—At the annual meeting of this society, held at Ottumwa, January 6, the following officers, all of Ottumwa, were elected: President, Dr. William B. La Force; vice-president, Dr. Charles R. Russell, and secretary and treasurer, Dr. Emma S. Powell.

O. A. Horr Medical Association.—At the annual meeting of this association, held in Lewiston, Me., Dec. 15, 1902, Dr. Wallace E. Webber, Lewiston, was elected president; Dr. E. A. McCollister, Lewiston, vice-president; Dr. Clarence C. Peaslee, Auburn, secretary, and Dr. John Sturgis, Auburn, treasurer.

South Texas Medical Association.—At the annual meeting of this body at Houston, Dec. 17, 1902, the following officers were elected: President, Dr. Hugh W. Crouse, Victoria; vice-presidents, Drs. John T. Moore, Galveston, and Sofie Herzog, Brazoria, and secretary and treasurer, Dr. Fred. B. Shields, Victoria.

Orange Mountain (N. J.) Medical Society.—The annual meeting of this society was held in Orange, January 9. Dr. Herman P. Gerbert, Orange, was elected president; Dr. Thomas S. P. Fitch, East Orange, vice-president; Dr. Richard D. Freeman, South Orange, secretary, and Dr. J. Minor Maghee, Orange, treasurer.

Huntingdon County (Pa.) Medical Society.—At the annual meeting of this society, held January 13, Dr. Bruce P. Steele, McVeytown (Mifflin County) was elected president; Dr. John M. Beck, Alexandria, vice-president; Dr. Howard C. Frontz, Huntingdon, secretary, and Dr. George C. Harman, Huntingdon, treasurer.

Medical Association of Porto Rico.—At the annual meeting of this association at San Juan, Dec. 14, 1902, the following officers were elected for a term of two years: Dr. Manuel Quevedo Baez, chairman; Dr. Jose N. Carbonell, treasurer, and Dr. Rafael Velez y Lopez, secretary, all of San Juan. The meeting was largely attended by physicians from almost every town in the island.

Portland (Me.) Medical Club.—The quadri-centennial of this club was celebrated Dec. 4, 1902. After a banquet and addresses by the retiring president, Dr. Arthur S. Gilson, on "The Advancement Made in Medical Science During the Past Twenty-five Years," and Dr. Frank W. Searle, the following officers were elected: President, Dr. Neil W. R. Straw; vice-presidents, Drs. Barzillai B. Foster and James K. Rogers, and secretary and treasurer, Dr. Herbert J. Patterson.

Philadelphia County Medical Society.—At a meeting of this society, held January 21, Dr. Francis M. Perkins was elected president; Dr. J. Cardeen Cooper, first vice-president; Dr. William S. Higbee, second vice-president; Dr. William S. Wray, secretary; Dr. Ross H. Skillern, assistant secretary; Dr. Collier L. Bower, treasurer, and Dr. William M. Welch, censor. Among proposed amendments to the by-laws, one making graduates of homeopathy eligible to membership was overwhelmingly rejected by the society.

St. Louis County (Minn.) Medical Society.—At the meeting of this society, held in Duluth, Dec. 11, 1902, the physicians of Lake, Cook, Carlton and Itasca counties were declared eligible to membership, the constitution having been so changed as to permit their admission. At the annual meeting and

banquet, January 8, Dr. John M. Robinson was elected president; Dr. Joseph D. Titcomb, first vice-president; Dr. Daniel D. Murray, second vice-president; Dr. Frederic J. Patton, secretary, and Dr. Clarence E. Lum, treasurer, all of Duluth.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Regular Meeting, held Dec. 10, 1902.

The President, Dr. C. S. Fenton, in the Chair.

Coal Tar Products in Neuralgia, Etc.

DR. WHARTON SINKLER called attention to the fact that when first introduced the coal tar derivatives were used solely as antipyretics, experiments with these preparations having shown their power of reducing temperature. It was observed, however, that they relieved the headaches and neuralgic pains accompanying the fevers for which they were administered, and they, therefore, soon attracted attention as analgesics.

The preparations first introduced, namely, antipyrin, acetanilid and phenacetin have remained the most popular among the various coal tar products, although a great many others have been put on the market. The writer gave a list of the painful affections in which these preparations were most efficacious. Among these are migraine, neuralgias of various kinds, the pains of locomotor ataxia and ovarian and visceral pains. He called attention to the fact that these preparations are of little value in pains of organic origin. He also stated that although these preparations have been greatly abused, the legitimate use of them has increased and that the confidence of the profession in them is greater at the present day than it even was several years ago.

Coal Tar Products in Central Nervous Affections.

DR. F. SAVARY PEARCE read a paper, pointing out the use and abuse of these drugs. The practical side of the indications for this class of remedies was presented from an experience of ten years in their use, together with data gathered from many physicians in different parts of the United States.

The functional central nervous diseases, hysteria and neurasthenia, were dwelt on. The danger in the continued use of antipyrin and similar remedies for pain in these affections lies in the fact that a drug habit may be established, as in one case detailed, wherein a young man had taken as high as 150 grains of antipyrin "for pain in the head," and he had employed 15 different physicians in the effort at cure, which was finally done by absolutely withholding the drug, assisted by suggestion. Trional was considered the best of the hypnotics, in 15-grain doses.

In organic central nervous affections the coal tar products should be used in brain tumor or as analgesics in meningitis, but guardedly so, since there is danger of collapse due to further depression of already inhibited action of the cardiac and respiratory centers in the medulla. It is well to guard the analgesic by incorporating into the tablet from 2 to 5 grains of caffein citrate. Phenacetin is the safest drug to employ in any case with cardiac weakness. In tabes dorsalis, the coal tar products have their most helpful use. Salol is valuable in autointoxications.

Coal Tar Products in Diseases of the Skin.

DR. MILTON B. HARTZELL presented this subject. Their use he considered a small one, the claims of the manufacturers not being justified. Their properties suggest a local effect inimical to the lower forms of life and an analgesic effect.

Coal tar itself is useful in chronic eczema; some dermatologists think it most effective of the coal tar products. Carbolic acid is the one most generally useful. It is not especially valuable for its parasitic effect, but more effective where itching is a prominent symptom. As an antipruritic it has no contraindications. The cresols are closely akin, and creolin or tricresol may be substituted for carbolic acid, but they are not so good. Resorcin, properly belonging to the coal tar products, is excellent in a lotion in seborrheic eczema; in acne it has no superior. A 40 to 50 per cent. preparation applied to superficial epithelioma will sometimes cause their cicatrization. It is valuable in chronic leg ulcers. Beta-naphthol is a parasitic remedy, a substitute for other drugs in scabies. It rarely causes irritation. The use of orthoform is liable to be followed by dermatitis, may be even gangrene of the skin. Acetanilid, with bland powders, used locally, may have a decided toxic effect and is not in general use. The internal use of this class of drugs in skin diseases is narrow in its limitations. Where itching exists antipyrin given twice daily may be of service. Phenacetin and acetanilid are sometimes excellent for the itching of urticaria. The coal tar products form a small but important addition to dermatotherapy.

DISCUSSION.

DR. J. P. CROZER GRIFFITH, in the discussion, claimed that there had been too great a rebound from the use of coal tar products in fevers. He held that they should not be used often, but he finds cases in which they must be used to get results, and to abandon them is a mistake. Often the nervous symptoms in children accompanying fever are well influenced by these drugs.

Electrolysis for Aneurism.

The last subject presented was by DR. H. A. HARE, "Another Case of Aortic Aneurism Treated by Electrolysis." This was the fourth reported by Dr. Hare. Altogether he has performed the operation eight times. The patient had been struck in the upper part of the chest with the pommel of his saddle. Dull, boring, aching chest pain developed within a few months. Cough and expectoration of blood ensued. An egg-shaped tumor developed in the superior portion and median line of the chest, and the left chest wall bulged prominently. There was a general heaving impulse with a bruit and the classical symptoms of a large aneurism.

Operation was performed July 10, 1901. A hollow needle was inserted into the tumor, through which 9 feet of gold wire were passed. An electric current, beginning with 5 milliamperes, was then sent through the wire. The current was gradually increased to 55 milliamperes, when pain was complained of, and the current was gradually reduced to 10 milliamperes. At the end of one hour the needle was withdrawn, the wire severed and the wound sealed with compound tincture of benzoin. Patient left the hospital several weeks after operation very much improved, and continued in fair health for two and a half months, when the aneurismal swelling suddenly increased greatly in size, in an area not having been wired.

Returning to the hospital, the portion wired six months previous was firm and hard. To the right of this area the rapidly-enlarging growth was wired in a manner identical with the first operation. The skin about the needle was so poorly nourished that it failed to heal over the opening, and slight oozing occurred, and finally a superficial slough formed. Repeated hemorrhages, usually in clots, some of them 3 or 4 inches long, took place from this external wound, and, as a result of a profuse one, the patient finally died.

The conclusions reached by Dr. Hare from his experience are as follows: Electrolysis in properly selected cases of aneurism is a valuable measure and prolongs life. The operation is neither dangerous nor painful.

The failure of permanent cure does not depend so much on the failure of the operation to limit the disease locally as to the fact that the adjacent parts of the blood vessel are weak and, when the most bulging area is solidified by the clot, these lateral areas may later on give way. Even in these cases life is prolonged by the closing of the weakest area and it is not to be forgotten that in at least one case (Stewart's) life was prolonged three years, death taking place from an alcoholic debauch.

DISCUSSION.

DR. D. D. STEWART stated that he had operated on many cases since 1889. He does not favor a current of more than 20 milliamperes, continued for three-quarters of an hour. If the aneurism is a large one he introduces wire in several places—has done so with good success. He uses gold wire. He considers it important that the wire have spring so that it will form a coil.

In closing, Dr. Hare stated that the tendency is to use less wire than formerly, 3 or 4 feet now being considered sufficient. He would use not over 30 milliamperes. He agrees with others in believing a permanent cure practically impossible. Occasionally laminated clots form spontaneously in aneurismal

sacs. The case was cited of a woman living in Philadelphia who has had for years a healed aneurismal sac as big as the fist protruding from the chest. Two points of warning in doing the operation were made: to see that the insulation is good or the skin will be injured, and to beware of too strong a current or the patient's back may be burned by the clay electrode.

Therapeutics.

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns without allusion to inquirer.]

Toxemia in Pregnancy.

According to *Prog. Medicine* pregnant women should be taught the necessity of careful attention during their pregnant state, and to this end the study, by the physician, of toxemia in its various phases should be carried out. One of the most important organs to the pregnant woman and the fetus is the liver. By regulating the liver and keeping it in a condition to perform its best work the physician can prevent much discomfort and perhaps puerperal convulsions. The liver, according to the author, must not be trusted to bear the strains of pregnancy and parturition without assistance. The patient, in addition to proper attention to diet and hygiene, should take a pill similar to the following once a day:

℞.	Eunonymin	
	Hydrarg. chloridi mit.	
	Pulv. ipecac., āā .....gr. 1/8	0075
	Aloin .....gr. 1/12	005
	Podophyllin .....gr. 1/20	003

M. Ft. cop. No. i. Sig.: One such pill at bedtime.

The foregoing pill should prove sufficient to cause one natural bowel movement daily. Different cases will require different amounts varying from one to three pills a day. This pill may be given for two weeks and omitted for two weeks.

Hyperchlorhydria.

Stockton, in "Text-book of Applied Therapeutics," states that when hydrochloric acid is present in the stomach beyond the normal limit, after a test meal, hyperchlorhydria exists. This condition coexists with motor disturbances generally. The treatment should be directed toward the cause and relief of the subjective symptoms. In order to relieve the suffering and distress of the patient the diet must be properly adjusted. Generally a milk diet affords comfort taken hot, but not boiled, with a little lime water, or peptogenic powder may be added.

About six ounces should be taken every two hours. When the stomach has had a short rest as the result of this diet and the irritability has subsided, a small amount of well-cooked starchy food may be added two or three times a day. Zwieback supplies this need most satisfactorily, as mastication becomes necessary and it is finely divided before entering the stomach. An egg may be added to the diet after a few days, and as these articles are added, the amount of milk should be decreased. Last of all meat may be added. This is best given at the evening meal, and milk should be excluded at that meal.

Within a week three meals of solid food may be permitted: The breakfast should consist of soft-boiled egg, a dry, warmed-over roll, and a bit of broiled bacon. In the middle of the forenoon a glass of hot milk should be taken; at the noon meal a large amount of Zwieback and a glass of hot milk; in the afternoon another glass of hot milk, and in the evening a plain, substantial dinner, which consists of the following: fish, roast beef or mutton, with fresh vegetables, but no dessert. Weak tea or coffee may be given at breakfast. All highly-flavored and seasoned soups should be omitted.

In addition to diet a great deal of good can be done with medicinal remedies. The condition of the liver and intestine must be inquired into when such marked disturbances of the stomach are present. In order to lessen the acidity and to allay the irritability of the gastric mucous membrane the following is recommended by the author:

℞.	Cerii oxalatis .....gr. xv	1
	Bismuthi subcarb. .....gr. xxx	2
	Magnesiæ (calcined) 3i	4

M. Sig.: One teaspoonful stirred in an ounce of water and taken at the first intimation of gastric distress.

This may be given as often as necessary through the day. The dose of magnesia if repeated too often will produce its laxative effect on the bowels, which is desirable within certain limits, but should not cause too frequent movement. In such cases the following may be substituted:

℞.	Cerii oxalatis	
	Bismuthi subcarb., āā .....gr. xv	1
	Bismuthi subgal.	
	Cretæ prep., āā 3ss	2
	Carbonis ligni pulv. 3i	4

M. Sig.: One teaspoonful stirred in water and then taken as often as necessary.

The two foregoing powders may be administered alternately in order to keep the bowels in the proper condition.

Chronic Constipation.

The medicinal treatment of chronic constipation, according to the *Encyc. of Med. and Surg.*, should consist principally of four drugs: Nux vomica or its alkaloid strychnia, aloes, jalap and cascara sagrada. The use of ergot and belladonna, according to the author, should be discontinued. And in case of evidence of atrophy of the glandular structure of the intestinal wall, this action may be increased by the administration of sodium phosphate and ammonium chlorid. Belladonna may be of service in those cases due to hyperacidity, but it should not be continued. For such purposes the following combination should be used:

℞.	Calcined magnesiæ .....ʒss	15	
	Pulv. rhei. .....ʒiiss	10	
	Sodii carb. 3i	4	
	Ext. belladonnæ		
	Ext. nucis vom., āā .....gr. ii		12

M. Sig.: One half a teaspoonful three times a day, half an hour after meals. And when atonic constipation is associated with absence of hydrochloric acid or subacidity the following:

℞.	Acidi hydrochlor. dil. .....ʒss	15	
	Strych. sulph. .....gr. 1/3		02
	Tinct. rhei q. s. ad .....ʒvi	180	

M. Sig.: One tablespoonful in a wineglassful of water one hour after meals through a glass tube.

When acute attacks of indigestion accompany the constipation, calomel should be given in half-grain doses repeated every two hours or castor oil may be substituted.

In stout individuals with inclination toward passive congestion in the intestinal canal, and hemorrhoids, the salines, such as sodium and magnesium sulphate, sodium and potassium tartrate and sodium phosphate are of service.

Nothnagel recommends the following:

℞.	Podophyllin .....gr. ivss		27
	Ext. aloes		
	Ext. rhei, āā .....gr. xlv	3	
	Ext. taraxaci .....gr. xx	1	30

M. Ft. pil. No. xl. Sig.: One pill at bedtime.

When flatulency is present the following pill is advised:

℞.	Ext. colocynth. co .....gr. 1/3	02
	Res. terebenthinæ .....gr. i	06
	Pulv. aloes soc. .....gr. iss	09
	Ext. nucis vom. .....gr. 1/4	015
	Ext. hyoscyami .....gr. i	06

M. Ft. pil. No. i. Sig.: One such at bedtime.

Strümpell recommends the following containing manna:

℞.	Mannæ		
	Sacchari, āā 3ss	2	
	Aq. fœniculi 3ss	2	
	Pulv. iris rad. .....gr. ii		12
	Olei amygdalæ dulcis .....gtt. xv	1	

M. Sig.: One heaping teaspoonful at bedtime for the bowels. Other preparations such as senna and the mineral waters may be substituted.

In gastrointestinal atony following fevers and in the stage of convalescence of summer complaints the following is recommended:

℞. Pulv. calumbæ		
Pulv. zinziberis, āā	℥ss	15
Pulv. senna fol.	℥i	4
Aquæ bullientis	Oi	500

M. Fiat infusum. Sig.: Take one wineglassful three times a day.

Psoriasis.

Chauneil of Paris, in the *Med. Press*, recommends that the animal food be reduced and that strong cheese, alcohol, and fermented liquids be omitted from the dietary. Proper amount of exercise should be taken to keep the skin in order.

The internal medication should consist of potassium iodid in large doses, commencing with 60 grains daily well diluted and increasing to one hundred and eighty grains. The treatment should not be continued longer than one month. He considers thyroid gland as a dangerous preparation in this trouble. The external treatment is of importance. The scales must be removed by a warm alkaline bath, the patient rubbing himself with a brush and soft soap.

Locally the following applications are to be employed:

℞. Olei cadini	℥ii	8
Saponis mollis q. s.		
Glycerol amyli	℥iii	90
Essent. caryophylli q. s.		

M. Sig.: Apply locally.

The foregoing may be gradually increased in strength and applied according to the following:

Olei cadini	℥iss	45
Saponis mollis q. s.		
Glycerol amyli	℥iss	45
Essent. caryophylli q. s.		

M. Sig.: Apply locally.

Pyrogallic acid should be used on small surfaces only, on account of the danger of intoxication. The same may be said of chrysophanic acid. Mercurial preparations, naphthol, salicylic acid are successfully employed as in the following combination:

℞. Acidi pyrogallici		
Ichthyol		
Naphthol		
Acidi salicylici, āā	℥ss	2
Vaselini	℥iii	90

M. Sig.: Apply locally.

Hebra recommended the following, containing oil of cade, in the treatment of eczema or psoriasis:

℞. Sulphuris sublim.		
Olei cadini, āā	℥ss	15
Saponis viridis		
Adipis, āā	℥i	30
Cretæ prep.	℥iiss	10

M. Fiat unguentum. Sig.: Apply locally. The following is recommended by Shoemaker, which may be varied in strength to suit the individual case:

℞. Olei cadini	℥vii	210
Tinct. quillajæ	℥v	20
Glycerol amyli	℥viii	240

M. Ft. unguentum. Sig.: For local application.

Arsenic in Chorea.

F. M. Pope, in an abstract in *Month. Encyc. of Pract. Med.*, gives the following principles for the administration of arsenic in the treatment of chorea: See that the tongue is clear before commencing treatment, and, if not, give a mild mercurial purge and a stomachic mixture for forty-eight hours. Put the patient on a bland and easily-digested diet. Give the drug in a much-diluted form and in the same dilution throughout. Do not discontinue on the first attack of vomiting, which may be due to accidental causes. Increase the dose daily. Keep the patient in bed throughout the treatment. If vomiting persists, discontinue the drug for twenty-four hours and then give the same dose as the last. Examine the patient very carefully every day for any sign of toxic action. What must be aimed at, according to the author, is a form of shock action on the nerve tissues, and this may explain the failure of long-continued treatment with small doses. A preparation containing iron in some form should be prescribed for some time after discontinuing the arsenic.

Medicolegal.

Missouri Supreme Court on Magnetic Healing, So-Called.—The Supreme Court of Missouri, Division No. 1, has reversed a judgment for libel obtained by Weltmer and others vs. Bishop on account of the publication in a newspaper of an article calling the former "miserable charlatans," and which was libelous if their business was legitimate, and if the statements were false, and if the article referred to them. The evidence on the trial showed, among other things, that the parties suing, who were men without the pretense of scientific learning, and who possessed only to a limited degree even the rudiments of education, were engaged in a business at Nevada, Mo., which they called "Magnetic Healing." They employed for chief assistants three men who were also unlearned in any science, and of little common education, and in addition to these a large number of female typewriters. They advertised very extensively in the chief cities of the United States and in foreign countries. In their advertisements they professed to possess miraculous power to heal all diseases to which beings were liable, without medicine and without surgery; that to them had been committed the startling revelation whereby all ailments are dispersed as if by magic; that they had cured patients thousands of miles away, and could cure thousands in an instant; that they exerted the same powers that Jesus Christ exerted to cure diseases 1900 years ago. By far the greater number of their patients were at a distance, and the only communication with them was by letter. These they proposed to cure, no matter what the disease, and though thousands of miles away, by a mysterious influence of the mind of the healer over that of the patient. The chief direction in the letter to the distant patient was that at a certain hour in the day he should dismiss all disturbing thoughts, and bring his mind into a passive condition to receive the influence from the mind of the healer, who at that same hour in Nevada would bring his mind to exert the mysterious influence desired. Their patients of this kind numbered many thousands, and they were treated by the typewriters, who alone read the letters coming from the absent patients, and answered them. The answer to each was, in the main, a copy of a circular letter prepared by the parties suing, and furnished the typewriters for that purpose. One of these parties, who was the originator of the scheme, and the chief director of the business, explained that the process of this absent treatment was that, at the hour designated in the letter in which the patient was to make his mind passive to receive the healing influence, he (the healer) would bring the powers of his own mind to bear on that of the distant patient, and the beneficial result would follow. In this way many hundreds of men, women, and children in different parts of the world were treated at the same instant. When his attention was called to the fact that at a stated hour in Nevada, when the healer was exercising his mind to transmit its influence to the expectant patients in different parts of the world, that time would not correspond with the hour in distant and different localities, he gave no clear explanation of the point. It was also shown that, when he left the business and went to Colorado for a summer vacation, this absent treatment went on as efficiently through the instrumentality of the typewriters as when the healer was present. One of the witnesses for the parties suing testified that she was a married woman, living near Chicago; that she had been afflicted with cancer of the breast, and other troubles peculiar to women; that she took this absent treatment from Professor Weltmer from May 1 to July 1, 1899, and was entirely cured. This was one of the cures effected by this absent treatment, when the healer was himself absent, and no one but the typewriter in Nevada to transmit the healing influence. The testimony as to the method of treatment of those who came in person to Nevada showed that it was, in the

main, an abuse of their credulity, and in some instances consisted only of disgusting suggestion. Quite a number of witnesses testified that they had taken these treatments, and were cured or benefited; and the trial judge submitted to the jury to say if the business was legitimate, and in weighing that question they were to consider the results as disclosed by the evidence, and, on the whole, if the results had been beneficial, the business was not to be adjudged a fraud. But the Supreme Court says that courts are not such slaves to the forms of procedure as to surrender their own intelligence to an array of witnesses testifying to an impossibility. They are not required to give credence to a statement that would falsify well-known laws of nature, though a cloud of witnesses swear to it. We, the court continues, recognize that in the realm of science much is yet undiscovered, and especially is this so in the science relating to diseases of the human system and their treatment. Different schools of medicine contend with each other on vital questions, and, as long as the contest continues with reason, it can not be said that the right of either, as above the other, has been demonstrated. But if either school would convince us that it is right, or even that it is entitled to be recognized as a contestant, it must appeal to our intelligence, and discuss the subject on the basis of natural laws. If it can not be discussed on that basis, there is nothing to discuss. If a man come into court claiming to possess supernatural powers, and bring with him witnesses who swear he has done for them that which we know is impossible, we are not required to believe such evidence. Here was a woman, who perhaps believed what she said, who testified that by a mental process of one of the parties suing, transmitted to her through a letter several hundred miles away, she was entirely cured of a cancer of the breast. The fact that the party who was supposed to have transmitted the influence from Nevada was not there at the time adds to the absurdity of the statement. And the testimony of other witnesses, perhaps also sincere, to the effect that they were cured of otherwise incurable diseases by such mysterious process, can have absolutely no lodgment in our intelligence. Under the instruction above referred to, the jury were directed to heed such evidence, and if, on the whole, it showed that good had resulted to the community from the practices of the parties suing, the jury were to find that the business was a lawful one. It was an instruction, in effect, directing the jury to surrender their own intelligence to the preponderance of statements of witnesses, irrational though such statements were. Under the conceded facts, there was no evidence to justify the submission of the case to the jury, and the peremptory instruction for a verdict for the party sued should have been given. If there was anything in the business of the parties suing, which they call "Magnetic Healing," that entitled it to the protection of the law, and which was not perceptible to the uninstructed, the burden was on them to show the rationale of it; and, failing to do so, the court should close its doors against them. The law of libel is not designed to shield one in the practice of an illegal business. The business of the parties suing, as shown by their own evidence, is of such a character as that it is not entitled to protection under the law of libel. On a motion for rehearing, the court's attention was called to the recent decision of the Supreme Court of the United States in the case of the School of Magnetic Healing vs. McAnnulty, reported on pages 122 and 123 of THE JOURNAL of Jan. 10, 1903. But the Supreme Court of Missouri points out that that case was very different in its facts from this one. In that case it was held that upon the statement of facts admitted by demurrer to be true the business of the complainants was not within the class forbidden to be conducted by use of the mails, but it was not meant to preclude it being shown on the trial, if it could be, that the business, as in fact conducted, amounted to a violation of the statutes. The decision in this case is not based on a demurrer admitting that the business of the parties suing is a system of healing conducted on practical and scientific principles, but it is based on the character of the business as shown by the evidence at the trial. Motion for rehearing overruled. All concur.

AMERICAN.

Titles marked with an asterisk (*) are abstracted below.

New York Medical Journal.

January 24.

1 The New York Academy of Medicine—Valedictory Address of the Retiring President. Robert F. Weir.
2 *A Study of the Deaths Occurring in New York City on the Opposite Sides of Twenty Streets During the Year 1895. Alfred E. Thayer.
3 Cases Illustrating Some of the Newer Points in the Surgery of the Day. Robert T. Morris.
4 Chronic Gastritis and Gastric Motor Insufficiency in Children. F. L. Wachenheim.
5 *The Treatment of Non-paralytic Strabismus, Including a New Operative Procedure. J. H. Woodward.

2. **Local Mortality.**—Thayer has studied the deaths occurring in New York City on the opposite sides of certain streets from 14th to 33d, selecting them mainly because of their larger proportion of individual residences and their east and west direction. He found that the mortality on the north side was decidedly higher than that on the south side. The excess of deaths was due chiefly to three diseases, pneumonia, phthisis and nephritis. The first two are specially fatal during cold weather, when the proper ventilation of living and sleeping rooms is most neglected. The third is also affected by lack of air and sunlight, and indirectly by mental depression due to darkness and poor air. On the south side of the street the greater freedom from these causes of death is chiefly due to the advantages of sunlight and ventilation enjoyed from the habit of New Yorkers of living in the rear part of the house, the south side residents thus having the better air and sunlight. Zymotic diseases appear to be independent of these conditions, and may occur in excess on the south side of the street, and the total mortality may be greater on that side. The rear houses are situated less favorably than the single houses on the lot, depriving the other house of its proper light and air also. The width of any street and the distance across yards, measured from the back of one house to the back of another, should be as nearly as possible the same; the latter should never be less than the former; and the height of dwelling houses should bear some relation to these measurements, so that one house will not deprive the other of its light and air. In the case of contagious disease in any family, the importance of keeping the other children from school is closely related to the question of infant mortality below the age of five years. In conclusion he urges people to keep their windows open and their shades up as much as possible, and this especially for dwellings on the north side of the street and during the colder months of the year when ventilation is most neglected.

5. **Stabismus.**—Woodward discusses the treatment of this condition and remarks that in his operations for strabismus he has confined himself in probably 90 per cent. to the deviating eye, and has advanced the opposing muscle in a great majority of cases, and in most of them cut overacting muscles. The result was an improvement on the practice of operating on both eyes, but yet it was not entirely satisfactory. In a smaller number of cases he has advanced the antagonist, omitting to divide the overacting muscle. Some of the results were gratifying. The chief difficulty encountered was that of maintaining the position of the advanced muscle until healing could take place. He devised a special needle that would neither tear nor cut the episcleral tissue, and was thus enabled to secure a hold that did not give way readily. Several methods of advancement were tried. Still, the pull of the overacting muscle on the sutures was always too great for security. Therefore, he tried to obviate that difficulty by stretching the overacting muscle, hoping to paralyze or weaken it temporarily. A strabismus hook was passed beneath the tendon and all the traction that seemed safe was exerted when the antagonist was advanced. He has tried this sufficiently to be convinced that stretching the tissues in this way will prove a very useful preliminary to advancement of the antagonist, and will later aid our endeavors to eliminate tenotomy from the treatment of strabismus.

6 *Influence of Nephrectomy Upon Absorption. S. J. Meltzer and W. Salant.
7 Secondary Carcinoma of the Liver, with Report of a Case in Which the Liver Weighed 15,110 gms. (33½ lbs.). Henry A. Christian.
8 *Through-and-through Intestinal Suture, with Report of Additional Cases. F. Gregory Connell.
9 *Transmissibility of Plague. W. J. Calvert.
10 Karyokinesis in Malignant Tumors. Frederick G. Canney.
11 X-Rays in Surgical Diagnosis. Arthur T. McCormack.
12 Widener Memorial Industrial Training School for Crippled Children. DeForest Willard.

6. **Influence of Nephrectomy on Absorption.**—Meltzer and Salant have experimented on nephrectomized rabbits, introducing salt solution through a fine opening into the peritoneal cavity and removing it very carefully again after varying intervals. A normal animal was used as a control test in each case. The first series of experiments was made with a 0.8 per cent. solution of sodium chlorid, presumably approximately isotonic with the normal serum of the animal. The result was a surprise. The nephrectomized animal usually absorbed not less than normal, but distinctly better. Nephrectomy seemed to rather favor absorption. This directed their attention to a factor which had been hitherto neglected in nephrectomy, the increased osmotic pressure of the blood, which should explain the phenomenon. In the next experiments they carried out several series with solutions of 1, 1.2, 1.5 and 2 per cent. sodium chlorid concentrations and found a still greater absorption in nephrectomized animals. With the solution of 1.2 per cent. of sodium chlorid the absorption was at least twenty-four times as good as that which took place in the normal animals. Their experiments show that after nephrectomy absorption is considerably improved. They clear up the mystery why no edema was observed after nephrectomy in animals or in pathologic conditions of acute anuria in human beings lasting sometimes five to six days. The first effect of complete anuria is not in the increase of the normal transudation but an increase of the power of absorption of the blood.

8.—See abstract in THE JOURNAL, xxxix, p. 1,132.

9. **Transmissibility of Plague.**—Calvert has experimented on the viability of plague germs and observed the transmission, which he thinks may take place through fleas and other insects as well as by inoculation. He reports a case of infection through the genitals and has experimented unsuccessfully on monkeys to produce plague by infusion through the mouth. In conclusion, he says that the plague organism is long-lived; is carried by raw materials, insects, etc.; gains access to the system through superficial abrasions, wounds and the pulmonary tract, and that a relatively small number of organisms may cause the disease.

13 *Cases Illustrating the Therapeutic Uses of the Roentgen Rays. Samuel B. Childs.
14 *Subphrenic Abcess as a Complication of Appendicitis. Henry A. Christian.
15 *A Consideration of the Scientific Application of Mechanical Vibratory Stimulation in the Treatment of Disease. Maurice F. Pilgrim.
16 *Tonsillitis Classified as an Infectious Disease. Walter S. Mills.
17 *The Medical Inspection of Schools: A Problem in Preventive Medicine. (Concluded.) Lewis S. Somers.

13. **Roentgen Rays.**—Childs illustrates a variety of cases and outlines the promise of this agent.

14. **Subphrenic Abscess.**—Christian and Lehr finds out of 86 cases of death due directly or indirectly to appendicitis, that 7 or 8.13 per cent. showed involvement of the subphrenic region in the purulent process. While not all these were primary abscesses, they review them as they think they will be of use in illustrating the manner of formation and the comparative findings of these conditions. They discuss the literature of subphrenic abscess, finding it not a very common disease and report several cases in detail, with autopsy and microscopic examinations. Subphrenic abscess, they say, secondary to appendicitis, may occur in one of four ways: 1. As a localized abscess or part of a general purulent peritonitis; 2, by extension of the disease process from appendix to subphrenic region by the intraperitoneal route; 3, by extension of this process by the extraperitoneal route either by the lymphatics or by infiltration through the retroperitoneal tissue; 4, by way of the blood current as part of a general embolic septic process, or as a sequence of liver abscesses which are of embolic origin, by way of the portal vein. The greater number occurred by direct extension intra- or extra-peritoneally. The right side seemed to be most involved. The pleura may become involved from the appendix by extension from a pneumonic focus or infarct, or by extension from the abdominal cavity by way of the lymphatics or by erosion of the diaphragm. This latter form constitutes the appendicular pleurisy of the French writers. It is very often associated with subphrenic abscess as in four of the seven cases reported, and is almost always right-sided.

15. **Mechanical Vibratory Stimulation.**—This method is applied for the stimulation of nerve and nerve centers, stimulating and equalizing the blood currents, and for the stimulation of the secretions and excretions, and the lymphatics. Pilgrim argues for its utility, claiming especially good results from this method in ocular affections due to anemia or hyperemia, in goiter, exophthalmic and other forms, functional disorders of the digestive function and varicose conditions, and looks for good effects in malignant growths. He has seen marked benefit from it in the early stages of tuberculosis, and cases of subacute rheumatism thus far treated have been benefited, and most of them cured. The same is true of neuralgia, myalgia, etc. In conclusion he describes a special instrument, which he thinks is best adapted for this purpose.

16. **Tonsillitis.**—The infectiousness of tonsillitis is argued by Mills. The paper is simply to call attention to the contagious nature of the disease and give it the proper place in classification.

17. **School Inspection.**—Somers' article is largely a review of what has been done in certain cities, Cleveland, Chicago, Philadelphia, and others, and the advantages that have been obtained from proper medical inspection in the prevention of epidemics, rectification of evils existing and aiding the defective and other children who are laboring under damaging conditions and surroundings.

18 *A Contribution to the Pathogenesis of the Uremic State; The Probability of Its Physico-electric Substratum. Heinrich Stern.
19 *Reasons for Believing that the Only Way in Nature for Yellow Fever to be Contracted by Man Is from the Mosquito. John W. Ross.
20 *Ankylosis of the Crico-Arytenoid Articulation, Due to Acute Inflammatory Causes. D. Bryson Delavan.
21 *The Relations and Treatment of Follicular Conjunctivitis and Trachoma. Ellice M. Alger.

18. **Uremic State.**—Stern holds it is made evident that the uremic state arises on the foundation of diminished electrical conductivity of the serum, or at least, that this is the potent contributing factor. A recapitulation of his article and remarks is given in the following:

1. None of the retained known products of metabolism are in themselves toxic to any degree.
2. In uremia there is a higher molecular concentration of the blood serum, which is due to the accumulation of normal products of catabolism.
3. Hyperosmosis of uremic serum is evidenced by determination of its freezing point. The freezing points of normal blood sera lie between -0.55 and -0.57° C., those of uremic blood sera are depressed to between -0.61 and -0.67° C.
4. The point of attack and the origin of the uremic convulsive phenomena is situated in the psychomotor centers of the cortex cerebri; the hyperosmotic condition of the blood and liquids in the brain may occasionally furnish the stimulus to the uremic attack, but there is no analogy between the degree of molecular concentration and the intensity of the uremic process.
5. In uremic serum there occurs invariably an abnormally large amount of retained nitrogen. There is no parallelism between the degree of freezing point depression and the amount of retained nitrogen.
6. Non-electrolytes do not only interfere with complete dissociation, that is ionization, but also retard ionic movement. Their presence, therefore, lessens the electrical conductivity of the watery liquid in which the electrolytes are contained.
7. In uremia the large amounts of retained albuminous derivatives exhibit most potent non-electrolytic qualities.
8. The ions as independent molecules participate in augmenting osmotic tension and in depressing the freezing point; the excessive high osmotic pressure of uremic serum is not due to its ions, but to its contents of neutral molecules.
9. Determination of the freezing point of uremic serum discloses the fact of its high molecular concentration, but not the degree of its electrical conductivity.
10. Dissociation of electrolyte molecules into ions occurs in the ratio of the dilution of the watery solution. The more concentrated the serum the smaller its conductive qualities.

11. The conductivity of the blood serum of healthy individuals varies between 106.18 and 119.12. The lowest conductivity of human blood yet found, 98.29, occurred in a case of uremia.
12. Intravenous injection of water for therapeutic purposes dilutes uremic serum in such a manner that it may exhibit greater conductive properties.
13. Normal conductivity of the serum is more readily and frequently re-established if the uremic state has developed on the basis of parenchymatous nephritis than if it occurs as the consequence of interstitial nephritis. A most potent reason for this is the fact of the existence of smaller amounts of retained nitrogen in the parenchymatous than in the interstitial type of the affection.
14. In most instances of uremia, especially in those characterized by deep and prolonged coma, the body temperature is considerably lowered. This fact again contributes toward reduction of serum conductivity. Elevation of temperature, on the other hand, as long as within well-defined limits, tends to increase the conductivity.

19. **Yellow Fever.**—Ross reviews the facts in regard to the transmission of yellow fever, restating those given by Reed, Carroll, Agramonte and others and remarking that while the attack made on the mosquito was thorough in Havana, other insect pests like bedbugs, fleas, etc., which are thought by some medical men to have some agency in the spread of the disease were not attacked at all, no attention being paid to such by the sanitary department. Nevertheless yellow fever was conquered. Yellow fever, he holds, is communicated through the mosquito, and through it alone.

20. **Crico-Arytenoid Ankylosis.**—This condition is not exceedingly rare, according to Delavan, and may be found in otherwise healthy subjects, a fact which he thinks should be more generally known. The majority of cases have been supposed to be due to perichondritis resulting from syphilis, gouty or rheumatoid arthritis, cancer and tuberculosis, but exanthemata, diphtheria and various traumatisms may give rise to them. Any acute inflammation of the posterior region of the larynx attended with infiltration may cause a temporary fixation of the crico-arytenoid joint. He reports cases illustrating the condition and discusses its diagnosis. In some cases it may be difficult to diagnose between this disorder and paralysis of the recurrent nerve, and only a careful process of exclusion may suffice to make it definite. Its prevention is not always easy, but certain prophylactic measures are worthy of mention, such as in typhoid fever, thorough and systematic cleansing of the nasal cavities and the mouth. Prevention is least effective in severe inflammation of the pharynx when it occurs. In most cases the fixation is not exactly in the median line, but a little to one side of it, the vocal band being in the so-called cadaveric position, thus rendering it less likely to interfere with respiration. He notices, in connection with the cases, a marked chest expansion that occurs in many of them, due to the necessity of greater effort to produce a given volume tone. All causes of local irritation should be avoided in this condition and proper chest gymnastics employed. "Taking cold" should be specially guarded against, and under fairly favorable conditions the majority of sufferers get along comfortably.

21. **Trachoma.**—Alger points out the differences between follicular conjunctivitis and trachoma, the symptoms being quite similar, but the former is only a trivial affection. We should depend on the presence of true conjunctival hypertrophy as a sign of trachoma. He gives the formulas for treatment of ordinary folliculitis, using simple solutions of ichthyol, iodin, glycerin applied to the conjunctiva, zinc sulphate and opiates, while in trachoma much more energetic measures have to be employed.

24 Cerebral Syphilis. Albert E. Brownrigg.
25 The Importance of Careful Examination and Frequent Cultures in Doubtful Throat Cases. W. P. Coues.

22. **Vaginal Celiotomy.**—Goffe holds that any operation that can be done through the vagina as well as through an abdominal incision is better done along the vaginal route. He thinks any pathologic condition that is confined to the true pelvis can be thus dealt with satisfactorily and with as permanent results and far greater safety than through the abdominal incision. His cases have embraced every variety of disease from simple retroversion to fibroid tumors and dermoid cysts. The method lends itself to every form of conservative work on the uterus and appendages that has been suggested in the trend of recent modern gynecology. He holds that it will grow in favor with experience. He describes his methods, favoring generally the anterior colpotomy method of opening as being less dangerous and liable to untoward and annoying consequences.

29 Spontaneous Rupture of the Heart, with a Report of Seven Cases. Arthur S. Hamilton.
30 *Atmospheric Pressure and Epidemic Influenza in Philadelphia. Howard S. Anders.
31 Legal Tests of Responsibility. Richard Webb.

26. **Tropical Diseases.**—Kieffer in this introductory lecture notices the lack of stamina of tropical natives, their insufficient nutrition, and the great advantage which the colonists in the tropics have over the native in the struggle for existence. He remarks that there are very few purely tropical diseases, but some of the common diseases undergo very strange intensifications and attenuations, thus measles is fatal to certain tropical populations, while scarlet fever and diphtheria may be mild and trivial. Leprosy is now particularly a tropical disease, because it is there unchecked. He notices as factors of disease, heat affections, infections which are largely the same as anywhere else, and only a very few that are peculiar; parasitic diseases which are numerous in the tropics, and he calls attention to alterations of type and malignancy. Tuberculosis in the tropical native is slow, though it may be virulent in a colonist. Other diseases like epithelioma seem to tend to chronicity. There is an "overlay" of filariasis over all diseases in the tropical native which mystifies the etiologic picture. It is not difficult to explain how this occurs when we note the customs of their agriculture. The problem of immunity is the same in one place as another. Acclimatization he considers consists in a re-adjustment of manners, morals and habits that effects a corresponding change in the organism to meet the new environment. The effects of heat are noticed in particular; the increase of body heat, the diminution of respiratory function, depression of digestion, appetite and assimilation, the greater activities of the skin function and depression of the nervous system.

28. **Six Years of Medical Journalism.**—Johnston writes amusingly and sensibly of medical journalism, noting the difficulties, temptations, and aggravations to which the medical editor is liable. He considers society proceedings largely superfluous, and speaks particularly of the difficulty of keeping up proper abstracts and the thanklessness of the work. He emphasizes the essential point of keeping the medical editorship absolutely divorced from the advertising functions of the journal.

30. **Influenza.**—Anders has studied the effect of barometric changes on influenza epidemics and gives tables to illustrate his paper. A comparative inspection and analysis of the figures of two groups of years, twelve of sporadic or non-epidemic years, and twelve of the epidemicity of influenza, fail to justify any generalization. A study of the mean maximums and minimums for the same group of months and years shows uniformly lower maximums and higher minimums of recorded means (monthly) for the epidemic, as compared with the non-epidemic group of years. We find that the monthly means of the greatest ranges of barometric record (between highest and lowest points) manifest nothing characteristic, but he has noticed in the Weather Bureau records that the greater monthly absolute range is a marked feature of severe influenzal periods as compared with mild or sporadic years, the difference amounting to as much as 0.4 inch higher for the epidemic months. Lastly, the suggestion is offered that any relation between meteorological conditions and the prevalence of influenza that may exist will probably be found in the sudden, frequent, rapid and extreme variations and alterna-

tions of the phenomena occurring on certain days, just before or simultaneous to the influenzal outbursts, and not in data of the means of large groups of monthly and annual recordings. It is the lack of equability in the absolute daily (sometimes almost hourly) extremes, and not in the monthly or yearly averages or means.

36 *The Physiological Action and Therapeutic Uses of the X-ray. C. M. Mutz.
37 To What Extent May We Hope by Treatment to Delay the Progress of Cataract? C. F. Clark.

35. **Syphilis in Women.**—The difficulties of diagnosis of syphilis in women are noticed by Williamson, the modified character of the chancre which varies with the tissue on which it occurs. The secondary symptoms are also different and confusing. Alopecia is apt to be slight and roseola likewise less prominent. The throat appearances may be variable and an uncertain guide. The sex is naturally lymphatic. This should be borne in mind in studying swollen glands and ganglia. Only in tertiary syphilis are the signs and symptoms the same in both sexes. Lastly, the cases are difficult to diagnose, because there is a natural tendency to deceive and conceal the condition which is perhaps stronger in women than in men.

36. **The X-Ray.**—Mutz thinks the *x*-ray a generally diffusible stimulant of the highest type, promoting the destruction of micro-organisms and inimical cells by increased phagocytic influence. It is not a universal germicide, however, and is certainly not an insecticide. He has not found its analgesic properties pronounced. Cataphoresis by the *x*-ray he considers dubious.

48 Posterior Dislocation of the Head of the Tibia. John G. Sheldon.
49 An Apparatus to Facilitate the Application of Plaster Jackets During Spinal Hyperextension. Erasmus D. Fenner.

38. **Tic Douloureux Operations.**—Abbe advocates interposition of a sheet of rubber tissue as a permanent barrier to the reunion of a divided intracranial nerve, and holds that it would in many cases make unnecessary such severe operations as removal of the gasserian ganglion. He thinks operations on the ganglion have been overdone, and that resection of one-fourth to one-half inch of nerve anterior to the ganglion and within the cranium, and interposition of rubber tissue can be relied upon for a perfect cure up to six years at least. The probability of permanency is as great as in any other method. It is a simple, speedy and safe method, and therefore fulfills the highest aims of the best surgery. He reports a case of six years' standing with good results.

39. **Basedow's Disease.**—Huntington advocates early operation, before destructive tissue changes have occurred and before the function of important organs has been seriously, perhaps permanently, impaired and the patient's vitality lowered by chronic thyroid intoxication. Complete bilateral extirpation should never be attempted. A small fragment of the least affected lobe contiguous to the tumor can be isolated and left. He also favors local anesthesia in the operation, and in three of the four cases reported this was employed with good results by the Schleich method.

40.—This article appeared in THE JOURNAL, xxxix, p. 1184.

41. **Renal and Hepatic Colic.**—Barnett attempts to show the close relationship existing between the pelvis of the kidney and the upper portion of the ureter on the right side, with the gall bladder, cystic duct, hepatic duct and communicating duct of the liver and the terminal ducts of the pancreas, with a sometimes similarity of symptoms from a pathologic invasion of any one of them, and more especially from stone formation. His paper is illustrated by skiagrams and illustrative cases, showing the difficulty of diagnosis between hepatic and renal calculus.

42. **Ligation of Arteries.**—Dawbarn advocates ligation of the arteries by the aid of a semicircular needle and holder, making a purse-string suture around the artery. The second part of his article deals with ligation of special arteries, of which he describes the technic.

53 *The Value of a Knowledge of Anatomy from a Practical Standpoint. Gwilym G. Davis.

50. **Rectal Nutrition.**—Edsall and Miller report their cases and discuss the condition at length, reviewing the literature. They say in conclusion:

> Rectal alimentation in exceptional cases provides enough food to the tissues to prevent tissue loss. Even in such favorable cases the best that can be done is to keep the patient from losing ground when he is already in a condition of decided subnutrition. Usually food administered per rectum is very imperfectly absorbed, and consequently rectal enemata, as a rule, supply only a very small part of the amount of food necessary in order to maintain a nutritive equilibrium.

51. **Floating Liver.**—Steele has experimented on cadavers to reproduce the conditions of floating liver so as to test the effects in inducing biliary obstruction. He found that the pressure rose steadily as the anterior border of the liver was allowed to sink, and at the lowest point was 2½ times that required when the liver was in its normal position. He goes to some length in explaining the conditions as they probably occur during life. In many cases the pressure is too transitory to permit of obstruction and absorption of bile, and the parts adjust themselves so that there is no kinking or torsion. The obstruction may not always be in the common duct. In conclusion he briefly reports cases, collected from the literature, of floating liver with jaundice without gallstones.

54. **Sarcoma of the Third Cervical Segment.**—The case described is considered unique for several reasons. 1. It is the only tumor of the spinal cord affecting the upper cervical region that has so far been recorded. 2. It is the only cervical cord tumor which has gone on to an uninterrupted course toward recovery. 3. It was definitely located and quickly removed without sacrifice of spinous processes and laminæ, and the short incision made a remarkably rapid closure. 4. The involvement of the phrenic nerve added an element of danger which was quickly removed during the progress of the operation. 5. From the surgeon's standpoint, it was located in the most inaccessible portion of the spinal cord, by virtue of the cervical curvature of the spinal column offering a concave field for operation instead of a convex. It was attached partly to the dura, and was about 2 cm. in length, and in diameter a little greater than that of a common lead pencil. The growth was not particularly vascular, but adrenalin solution was applied as a matter of precaution and the surgical recovery was perfect.

55. **Ovarian Embryomata.**—The subject of ovarian teratomata is discussed at length by Jelke, who favors the theory advanced by Wilms that the condition is not of congenital origin, but is of ovulogenous derivation. Three cases are reported. Structures from the three embryonal primordial layers were found in each of them, with the exception of one, and here advanced degeneration of the tissues interfered with the absolute distinction of tissues. In none of the specimens were there any fetal inclusions or remains of congenital malformations found.

56. **Adrenal Tumors.**—Woolley gives a general description of adrenal tumors, and details the varieties. He concludes with a tabulated statement of 22 primary carcinomatous tumors and an extensive bibliography.

57. **Adrenalin Glycosuria.**—Herter and Wakeman give an account of an experimental investigation which seemed to show that there is a close relationship between the adrenal glands and the carbohydrate metabolism. They do not deem, however, that we have as yet succeeded in obtaining unequivocal evidence that the phenomena described are due to excessive influence of the adrenal internal secretion or to the exclusion of this secretion from the circulation. They suggest that some of the phenomena can be accounted for by the imperfectly understood nervous factors in play. Further experiments are required to determine whether the internal secretion hypothesis is tenable.

59. **Eosinophilia in Pelvic Lesions.**—The following are Weir's conclusions:

1. Eosinophiles take a prominent part in the cellular infiltration associated with inflammatory and suppurative processes of the pelvic organs. 2. In such conditions they usually occur in the largest numbers in the subacute stage and associated with connective tissue hyperplasia. 3. Eosinophilic infiltration is found in most cases of carcinoma of the cervix and in almost all cases of pyosalpinx and ovarian abscess. 4. In inflammatory conditions of the endometrium eosinophiles occur in small numbers and in but few cases. 5. Eosinophiles represent a large proportion of the cells forming the stroma of the mucosa in the normal and the diseased appendix. 6. In inflammatory conditions of the pelvic organs associated with an eosinophilic infiltration of the tissues the percentage of eosinophiles in the circulating blood is rarely increased, and usually decreased.

60. **X-Ray Tissue Changes.**—The article by Ellis is largely a discussion of the literature and report of careful examinations of cases. A study of the cases shows: 1. Necrosis of cells and trabeculæ of varying degree, and in one also marked fatty degeneration. 2. Increase of elastic tissue in the three cases examined, both before and after exposure. 3. Fewer areas of lymphocytic infiltration in one case after exposure, about equal numbers in others. 4. A tendency to occlusion of vessels by deposits on their inner surfaces, marked in some instances, not so prominent in others. 5. Practically entire absence of infiltration by polymorphonuclear leucocytes. While these results do not warrant conclusions, especially as further studies are being made as regards the nerve and blood changes, he offers the following suggestions:

1. Beck and others lay great stress on blood vessel changes as the cause of necrosis. While endarteritis is probably induced by the *x*-ray, the accompanying tissue necrosis seems out of proportion to the vessel changes, suggesting the possibility of these being *pari passu* results of the same influence, instead of cause and effect.
2. The presence of immense numbers of cocci and bacilli in the tissues of Case 3, after twenty exposures to the *x*-ray, would argue against the possession by that agent of bactericidal power. It should be said that the pathogenicity of these micro-organisms was not proven.
3. The unsatisfactory clinical results as well as the slight microscopic changes in Case 3 can probably be safely attributed to the presence of the exceedingly numerous keratinized areas or pearls. This emphasizes the importance of curetting or cutting away diseased tissue, whenever feasible, before instituting treatment by the *x*-ray.

61. **Paracolon Infection.**—Three cases are reported by Allen with bacteriologic data and agglutination tests. He says while no definite conclusions can be drawn regarding the pathology of the disease, it is evident that we have in it a distinct infection from that of typhoid fever.

62. **Malta Fever.**—Craig reports cases occurring in the American soldiers, and reviews the other papers that have been written on the subject from the same point of view. He says the following conclusions may be drawn from a study of these cases:

1. There occurs in the tropics and sub-tropics a fever which may resemble in its acute stage either typhoid or malaria, and in its chronic stage articular rheumatism, caused by the *Micrococcus melitensis*. 2. There are no pathognomonic symptoms of Malta fever. The symptoms observed are so inconstant and confusing that no one of them can be said to be typical of the disease. 3. A differential diagnosis of this fever is almost impossible in the majority of cases without the aid of the microscope and the serum test.

63. **Multiple Serositis.**—Kelly points out the diagnostic differences between multiple serositis and other ascitic conditions, remarking that special attention should be directed to the following points:

History of previous attacks of acute pericarditis, pleuritis, peritonitis, perihepatitis, to the early occurrence of subsequent disorders, edema of the legs, to marked ascites with little or no edema of the legs, enlarged liver early in the course of the disease, absence or very late appearance of marked enlargement of the spleen, a tendency to the occurrence of repeated attacks, pain, tenderness, rigidity and possibly palpable and audible frictions in the right hypochondriac region, attributable to perihepatitic attacks, to the rapid recurrence of ascites after tapping, and to the physical signs of adherent pericardium, which are essential to the diagnosis.

In the diagnosis of adherent pericardium most help will be derived from a weak or absent apex-beat, especially in cases in which there is no increase in the area of cardiac dulness, systolic retraction of a considerable area about the apex, systolic retraction of the base of the left chest posteriorly, arrest of the normal respiratory movements in the epigastric angle, imperfect descent of the apex-beat during inspiration and the absence of change in the limits of the cardiac dulness during respiration, absence of increase of the cardiac dulness to the right, despite marked engorgement of the veins of the neck; a diastolic shock or rebound of the heart; evidences of dilatation or hypertrophy of the heart in the absence of valvular or other disease that might cause it; absence of the characteristic changes in the heart in the presence of definite valvular disease—that is, absence of the usual hypertrophy of the right ventricle in mitral disease and of the left ventricle in aortic disease; absence of pericardial effusion in the presence of pleural and peritoneal effusions; paradoxic pulse—inspiratory diminution in the force and volume of the pulse; diastolic collapse and inspiratory swelling of the veins of the neck; and, as suggested by Musser, the non-occurrence in young subjects with valvular disease and cardiac insufficiency of the characteristic improvement following the administration of digitalis. None of these is pathognomonic of adherent pericardium; all will not be present in every case; but in many cases a sufficient number may be present to warrant the diagnosis. Finally, this obliterative pericarditis with ascites may be distinguished from cirrhosis of the liver; by the aforementioned symptoms and signs of adherent pericardium; by the absence of etiologic factors of cirrhosis of the liver; by the slow, insidious, protracted and intermittent course of the disease; by the long periods of standstill during which the ascites may remain stationary and the patient in good condition; by the entire absence or the transient presence of slight jaundice; by the absence in most cases of portal congestion and gastrointestinal disturbances—hemorrhage, diarrhea, hemorrhoids, enlargement of the spleen, marked dilatation of the superficial veins of the abdominal wall, etc.; in some cases, by the association of an enlarged, smooth, and firm liver, with marked ascites; and by the fact that in many cases the patient survives a large number of tappings.

64 *On Amaurotic Family Idiocy. A Disease Chiefly of the Gray Matter of the Central Nervous System. B. Sachs.
65 *The Postero-lateral Scleroses. Charles W. Burr and D. J. McCarthy.
66 Paralysis of all Four Limbs and of One Side of the Face, with Dissociation of Sensation, Developing in a Few Hours and Resulting from Meningo-myelocephalitis. Charles K. Mills and William G. Spiller.

64. **Amaurotic Family Idiocy.**—Sachs reports a case with necropsy findings, and discusses the condition. He thinks it indicates that the disease affected primarily, or at least to a great extent, the entire gray matter of the brain and spinal

cord, an abiotrophy, as Gowers calls it. There is a deficient vitality of gray matter of the central nervous system. He does not claim that all cases are identical, but it seems to him that the most reasonable inference is that in amaurotic family idiocy the entire central gray matter is the seat of intense degeneration, and that somewhat similar changes are found in conditions more or less closely allied to this special type of family disease. He thinks the subject should be carefully studied and every new case fully reported, with special attention to changes in the gray matter of the brain and spinal cord.

65. **Postero-Lateral Scleroses.**—Burr and McCarthy report several cases, with examinations, and note the difficulty of proper classification. They offer the following classification for clinical and laboratory purposes:

1. Friedreich's ataxia. 2. Tabes with associated diffuse sclerosis extending into the lateral columns. To this group may be added those cases of tabes associated with paretic dementia with secondary lesions in the crossed pyramidal tracts. 3. Tabes with degeneration in the crossed pyramidal and also in the direct cerebellar tracts, with or without degeneration in Clarke's column. 4. Posterior sclerosis with sclerosis of the lateral columns and disease of the anterior horns. (Chronic poliomyelitis.) 5. Primary lateral sclerosis with minor changes in the posterior columns. 6. Subacute diffuse degeneration of the spinal cord, due to anemia, cachexias, sepsis, etc., with sclerosis in the posterior and lateral tracts predominating, both in clinical manifestation and under the microscope. 7. Diffuse interstitial sclerosis, seen occasionally in chronic alcoholism with multiple neuritis, in which the parenchymatous degeneration is secondary to the overgrowth of glial and connective tissue elements. To this same group on account of similarity of the pathologic process may be added the syphilitic postero-lateral scleroses secondary to meningeal lesions. 8. A combined system disease of unknown origin, affecting the posterior and lateral columns, and distinctly confined to the direct and crossed pyramidal tracts and the posterior columns; the direct cerebellar tract may also be involved.

70 *On Certain Precautions Required in Making and Interpreting the So-called "Colon Test" for Potable Waters. Samuel C. Prescott.
71 Centenarians in Massachusetts. J. M. French.

69. **Gastric Cancer.**—The symptoms are reviewed by Benedict. He warns especially against the use of age and duration of the disease in making the diagnosis. Cancer at about 30 is by no means rare, and he says patients may have what their former attendants call malignant cachexia for many years, and have continued well in spite of it.

70. **The "Colon Test" for Potable Waters.**—Prescott recapitulates the points made in his paper as follows:

1. Bacteria corresponding in every way to *B. coli* are by no means confined to animal intestines, but are widely distributed elsewhere in nature. 2. The finding of a few colonies of *B. coli* in large samples of water, or its occasional discovery in small samples does not necessarily have any special significance. 3. The detection of *B. coli* in a large proportion of small samples (1 cubic centimeter or less) examined is imperatively required as an indication of recent sewage pollution. 4. The number of *B. coli* in water rather than their presence should be used as a criterion of recent sewage pollution. 5. Inasmuch as some red colonies other than those of *B. coli* appear on a litmus-lactose-agar plate, this test alone cannot be regarded as diagnostic. 6. In tests for the presence of *B. coli* by the usual methods the possible inhibitory effect of lactic-acid-producing streptococci must not be overlooked.

81 *Sclerosis of the Mastoid Process. Otto J. Stein.
82 A Curious Case of Emphysema. G. G. Taylor.

75. **Pernicious Anemia.**—Billings describes elaborately the spinal changes of pernicious anemia in severe cases, and offers general remarks on the condition. The conclusions which he draws are:

1. That there is a well-established relation of diffuse cord degeneration with pernicious anemia. 2. It seems probable that the hemolysis and the cord changes are due to the same toxin. 3. While the source of the toxin is unknown, the fact that gastro-intestinal disturbance is so common in the disease would lead one to suppose that it is of intestinal origin. 4. The diffuse degenerations of the spinal cord which occur in conditions without pernicious anemia do not appear to differ essentially from those of pernicious anemia. 5. It is possible that a common blood circulating poison exists, which may expend its force upon the blood in one individual, upon the nervous apparatus in another, and coincidently upon the blood and spinal cord in others.

83. **Morphin in Eclampsia.**—The editor of the *Therapeutic Gazette* has sent out letters asking for opinions as to the value and utility of morphin in uremic convulsions. Answers are published from Drs. James Tyson, W. Hale White, William Ewart, Frank Billings, John H. Musser and James M. Anders. The general opinion seems to be that morphin is harmful in most conditions, especially in interstitial and chonic nephritis. It is only in cases of acute parenchymatous trouble that it may be of value, and then in moderate or very small doses. Still, there is some difference of opinion as to its exact application. Billings considers it a cardiovascular tonic and of great value in cases where there is dilatation of the heart with vasomotor stasis and a tendency to lung edema. He would give strychnin in connection with morphin. Musser has seen it apparently useful in one or two cases of chronic interstitial nephritis.

92 Obstetrical Technique in General Practice. Z. Taylor Malaby.

91. **Chronic Follicular Urethritis.**—Eaton describes the method of treatment adopted by him, which he thinks is simple and effective. He first had a canula made, 20 cm. long, No. 20 gauge, curved at its proximal end, with a smaller curved point, which can be introduced direct into the orifice of the ducts. This is attached to a syringe and a urethroscope of not less than 25 French scale introduced into the urethra. He first irrigates the urethra with saline solution before inserting the urethroscope and then applies a 50 per cent. peroxid of hydrogen solution directly into the follicles, through the point of the canula. After all the observable glands have been treated, he again irrigates the urethra, then reintroduces the urethroscope and re-treats each gland with a 5 per cent. solution of albargin. Finally, he again irrigates the urethra with normal saline solution for the third time, before the injections and after. He thinks many cases thus treated will be permanently relieved of urethral irritation.

103 *Preliminary Note on a Method of Resuscitation of Apparently Recently Dead Animals. George W. Crile.

98. **Tuberculosis.**—Warner says the conditions which favor the introduction of consumption are: 1. Concentration of poison, modified by ventilation and environment; 2, intimate association and prolonged contact with a tuberculous individual; 3, ill health, especially the result of exhausting and debilitating diseases; 4, feeble power of resistance, known as hereditary tendency; many people are born with a phthisical tendency, and have a special susceptibility to the infection; 5, slight acclimatization of the individual to the tubercular infection; 6, occupation; 7, diet, and 8, climate. He recommends a better attitude of the public toward victims of tuberculosis, who are not dangerous if they take proper care of themselves.

155. **Peribronchitis and Interstitial Pneumonia.**—Jacobi suggests that so-called interstitial pneumonia, or what he prefers to call pulmonary hyperplasia with secondary sclerosis, is frequently an independent disease, and that full recovery from it is by no means an uncommon occurrence; that, indeed, a certain degree of pulmonary cirrhosis is not an obstacle to comfort and activity. He details the differential diagnosis. The best preventive is the avoidance of infection and colds. We can do much medicinally with tissue builders, arsenic, phosphorus, etc.; the equivalent of a grain of digitalis given daily, for several months in succession. A baby of a year may take ten drops of the elixir of phosphorus of the pharmacopeia three times a day for three months in succession. Children of 5 to 7 years who do not thrive on that treatment and get iron enough in their food should be suspected of a parasyphilitic infection. He speaks in conclusion of the advantages of climate and outdoor life.

1. **Calculus.**—Harrison notices the various geographical distributions of calculus and its origin. He agrees with Rainey's views as to formation, but says, while the presence of material is necessary, other conditions must exist. Geographical considerations indicate that there may be in certain places a fortuitous concurrence of conditions that effect a concretion of the normal or abnormal supply of concretable matter in the individual. This indicates the possibility of preventing local conditions. Certain mineral waters, for example, while not reducing the amount of uric acid in the system, seem to prevent its concretion. He mentions drugs such as sodium salicylate and benzoate, urotropin and boracite and what was called in olden times "Dutch drops," being a mixture of oil of turpentine, tincture of guaiacum, spirit of nitric ether and small portions of the oils of amber and cloves. From a trial of this latter he has no doubt of its efficacy. It can be conveniently taken in capsule form. Some years ago his attention was called to a salt called boracite, which he thinks is well worth attention in the preventive treatment of calculus. He has employed it in the last two years, and reports a case showing its success in disintegrating a kidney concretion.

13. **Anesthesia.**—Hewitt's second lecture deals first with bad subjects for anesthesia where the cause is due to some embarrassment of respiration, such as post-nasal growths, enlarged tonsils, fixity of the lower jaw, angina Ludovici, etc. In these cases all asphyxiating anesthetics are to be avoided. Pure nitrous oxid may be a poison in angina Ludovici, while the abuse of ether may also have a bad effect. They are best treated by a slow administration of a mixture of ether and chloroform with plenty of air, only moderate anesthesia being advisable in the worst cases. Where there is general bronchitis, tracheal stridor, orthopnea and some lividity, it may be hazardous to administer chloroform, even in analgesic doses. He has on two occasions known a lengthy administration of chloroform to an elderly patient with chronic bronchitis to be followed by fatal increase of the disease, and this points out a danger not always realized. Patients who have been confined to bed with some constitutional disease are not, as a rule, bad subjects for anesthesia, but it does not follow that a smooth anesthesia will be obtained. Much seems to depend on the type to which the patient belonged before his illness and the duration of the malady. The robust man who has suffered from appendicitis may not be a good subject. Patients suffering from heart disease are not bad subjects, provided the methods employed are suitable. Air-limitation in these cases must be practiced with caution, and he thinks even the administration of pure nitrous oxid contraindicated in the more advanced forms of heart affections. Many difficulties are explained by the assertion that the patient was nervous. He doubts whether mental disquiet leads to any great trouble, but in a few cases he has satisfied himself that the patient's nervous state has given him some trouble, and large quantities of anesthetic may be required. Alcoholic subjects are notoriously bad ones. Hewitt remarks as to the special influence of the excessive use of tobacco in making the anesthesia difficult. There is likely to be considerable spasm of the jaws in some cases, which he suggests may be due to suction, puffing and other movements, essential to the smoking of a pipe, and causing muscle hypertrophy. If in any case we find two, three or four of these conditions associated, the difficulty is naturally increased. The pure types are not common. Athletes frequently have nasal obstruction, which, with good muscle development and good teeth, may produce considerable trouble. If excessive smoking has also been the habit, the case will be still further embarrassed; similarly with drinking. In some of these cases the tongue has to be drawn forward while chloroform, the only possible anesthetic, is given. If there is grave constitutional disorder existing, as, for example, in a stout, breathless old man, an excessive smoker and drinker, suffering for years from nasal polypi and seized with acute intestinal obstruction, no worse subject can be imagined. He advises putting these patients on their side and using chloroform and ether mixture or the A. C. E. mixture to begin with, substituting for it ether when the anesthesia is continued. Lastly, he mentions cases where no cause is evident for the trouble, and he warrants the retention of the term idiosyncrasy for such cases.

15. **Chronic Obstruction of the Cecum and Ascending Colon.**—Lane calls attention to a condition which he thinks often is responsible for obstruction to the free passage of the intestinal contents, namely, angulation or semi-kinking of the hepatic flexure, due to a mal-development of the mesentery. He thinks that in a certain proportion of cases of so-called appendicitis the primary factor is just this condition, and that the trouble in the appendix is a secondary matter. The symptoms, of course, vary within wide limits, according to the different conditions, producing sometimes complete intestinal obstruction and in other cases either pain or uncomfortable sensation along the last dorsal, ilio-hypogastric, and ilio-inguinal nerves with dragging in the loin and tenderness on pressure or on percussion immediately below the last rib posteriorly. These suggest renal trouble, and mistakes may be made. The assumption of the recumbent posture and free purgation generally relieve these cases, but they may recur for many years. He thinks the habit of removing the appendix through a very small incision is injudicious. In the conclusion of his paper he describes his method of nephropexy, exposing the kidney with an oblique incision in the loin, freeing it from fat, and stripping the capsule on one side from its lower two-thirds in the form of six triangles, the bases being left intact. Each of these flaps are twisted up, and a piece of sterile silk twist is tied securely to it. The kidney is replaced within the abdomen in such a position that little more than one-half is exposed below the left rib. Needles are placed on each silk thread, and they are passed through the last intercostal space and through the abdominal muscles within an inch of their cut margins, so as to bring the raw surface of the kidney into apposition with the deep surface of the muscle wall freed

from fat and fascia. When these sutures have been secured the resistance offered by the capsule is sufficient to require the expenditure of a considerable amount of force to displace the kidney from the position in which it is fixed. The incision in the muscle wall and skin are then accurately closed. In this operation, as in any other requiring buried sutures, the surgeon should be exceedingly careful that no ligature left in the wound has been touched by the hand on any excuse whatever. He has never seen the method fail.

16. **Cyanosis.**—Gibson discusses cyanosis and reports cases and he recalls a former article in which he had explained the phenomena by assuming an increase of red corpuscles and hemoglobin, being due to diminished waste from lessened metabolism, and hence longer vitality of the cells. He reports two cases in which attempts were made to ascertain the effect of oxygen inhalations on the cyanosed condition, which would seem to indicate that they are barren of result.

19. **Fibroids.**—Bond analyzes fifty cases and concludes that the decision as to operation in fibroid disease of the intestine must depend on the danger to life and the amount of disablement, ill health and suffering which are caused by the disease. The social position of the patient may have to be largely considered, and where an invalid life can not be supported comfortably operation is more imperative. The operation of abdominal cervical hysterectomy as now carried out has a lower mortality in capable hands than is sometimes represented (4 per cent.), and may be compared with that of ovariotomy. The uterus can be safely amputated at any level, and the absence of recurrence of fibroid disease in the stump of the cervical portion of the uterus—in any case in the present series—is an argument in favor of cervical amputation as against panhysterectomy. It also leaves the pelvic floor intact. Myomectomy with preservation of the uterus as a whole is a conservative operation of much value, and should be practiced in the case of single and excessive tumors. In all cases where possible one or both ovaries should be left in the operation of hysterectomy for fibroid disease. The benefits are shown in a more complete convalescence and the modified character of the artificial menopause.

20. **A New Film Dressing for Wounds.**—Beale remarks that if we were to practice aseptic surgery and treat all wounds so as to give them the benefits of light and air it would be of great advantage. The next best thing would be hermetic sealing of a wound with some material which is aseptic and upon which we can apply as much pressure as necessary. If such substance were transparent he thinks it would be an ideal dressing. He says that within the last twelve months he has been using a thin film of substance called "velvril," one of the cellulose derivatives, which seems to be exceedingly satisfactory in many respects. It is easily applied and easily taken away, and yet is capable of causing hermetic sealing of the wound. He thinks that it will supersede protective (oil-silk), thin mackintosh and gum-elastic in surgical practice. It is practically indestructible and constant in composition at all ordinary temperatures. It is also used in solution, which is a valuable addition to its utility.

22. **The Pneumococcus.**—Sinigar reports an epidemic occurring in the Leavesden asylum, which seemed to show clinical evidence of variability in the virulence of the pneumococcus. During the height of the epidemic the fatality was very large among those attacked, while later, though the pneumococcus was numerous, the epidemic subsided. He thinks they were dealing with a pneumococcus which was at first of low vitality, then gradually increasing in severity, causing a more protracted illness, with occasional bronchial symptoms, and culminating in a case of lobar pneumonia in a nurse. At the time the female patients were taken with it its virulence was such that pulmonary symptoms were again in evidence. Short vague illnesses were few. Still the pulmonary signs were only those of patchy consolidation. When the utmost virulence was reached most of the cases were true lobar pneumonias, with a high mortality. Altogether 13 nurses, 17 male attendants and 43 female patients were attacked; the number of male patients attacked was not recorded. The pneumococcus, therefore, he thinks, may be changed from being a harmless resident of the mouth and nose to a virulent pathogenic organism. This last condition may be started up from the former.

23. **The Mimicry of Gastric Troubles.**—Treves reports several cases where the symptoms strongly indicated gastric troubles, and yet there was no gastric disorder. In one of the cases there was the deformity of old Pott's disease, and probably a slight recrudescence and rest in bed for a considerable period relieved the symptoms. Another one turned out to be one of sarcoma in the dorsal region of the spine. The moral to be derived, he says, is that suspicion may be aroused as to the genuineness of the gastric trouble when the pain is the all-predominating symptom, when it is intense and persisting, and when vomiting is at the same time either absent or insignificant.

25. **Tuberculosis.**—Philip calls attention to the significance of the supraclavicular triangle in relation to early changes in the lungs and the best line of percussion for the determination of slight degrees of apical involvement, and lastly the value of what he terms "tidal percussion." The normal upper limit of the lung resonance, he claims, reaches one and a half to two inches above the clavicle, and he gives illustrations. The best line of percussion for a slight obstruction of the apical involvement is described by him as follows: The pleximeter finger of the left hand is placed across the apex of the lung from back to front, approximately in a plane at right angles to the vertical diameter of the lung. Percussion is practiced with the middle finger of the right hand in a direction at right angles to the pleximeter. The percussion strokes should be firm and sharp, but not too strong. The finger should be laid a little above the clavicle, one and a half inches or more. What he calls "tidal percussion" is the practice of percussion more particularly at the apices, alternated during expiration or easy respiration and during full inspiration, which is quite markedly different in the healthy subject and in conditions of slight involvement. The value of "tidal resonance" is also remarked in observation of the course of the disease, and if it becomes arrested considerable improvement in tidal resonance is frequently to be noticed, and this return is a most satisfactory indication.

51. The Ganglia in Infectious Diseases.—In 1900 Van Gehuchten discovered certain lesions in the peripheral nervous ganglia of animals dying from rabies, and accepted them as a means of differentiating the disease. Attempts to reproduce the lesions in animals were undertaken by Goebel, but failed. He has, however, discovered the same lesions in the ganglia of the pneumogastric in various chronic infectious diseases, in syphilis and tuberculosis in particular. The lesion consists in the disappearance of certain of the nerve cells in the center of the ganglion and their substitution by small round cells. These cells result from the proliferation of the elements of the endothelial capsule entailing the destruction of the nerve cells. The lesion was as pronounced in one case of syphilis, in particular, as has ever been observed in case of rabies. Goebel explains it as the result of the phagocytic activity of the endothelial cells exerted against the nerve cell when the latter is suffering under the influence of some toxin and thus its normal resisting balance disturbed. It is not specific for any one disease; Crocq noted it in a case of true croup. It is of the same nature as the histologic alterations observed in the intoxication of tetanus and botulinic intoxication.

52. Biologic Study of Process of Growing Old.—We remember Metchnikoff's announcement in 1901, that the blanching of the hair is the work of certain ameboid cells, pigmentophages or chromophages. These elements become stimulated to action by the influence of some yet unknown cause and at a certain moment commence to "swallow" the pigment granules in the hairs and deport them into the skin or away from the organism. Research in this line is rendered difficult by the fact that animals are short-lived and the process of growing old in a dog or horse, for instance, can not be compared with that in man, as their life cycle is complete in twenty-five years at farthest. Parrots live much longer and Metchnikoff has been studying some whose captivity is known to have extended over eighty years. Two were of the family of *Chrysotis amazonica*. One of these was a male, apparently healthy, sexual appetite well preserved, coloring of plumage brilliant, known to be over 70. In another the plumage was brilliant but scanty. The organs showed no lesions, but the central nervous system was the seat of an intense phagocytosis. The nerve cells were surrounded by neuronophages. The latter did not seem to "swallow" the nerve cells, but merely to suck out their contents. He observed a similar nerve cell destruction in a parroquet which died at 20, not from old age but probably from some food intoxication. In the aged parrot it was evidently the result of senile degeneration which may likewise be considered the consequence of a chronic intoxication. The results of this research on parrots confirm those obtained in mammals.

53. Improved Vaccination Against Plague, Cholera and Typhoid Fever.—Besredka proclaims that he has produced a vaccine which combines the advantages of serum treatment and Haffkine's method, and yet is free from either local or general reaction. The immunity conferred commences in twenty-four hours for cholera and typhoid fever and in forty-eight for the plague, while it lasts for five and one-half months at least, and possibly much longer. An emulsion is made from microbes scraped from the surface of a forty-eight-hour gelose culture, and heated on the water bath to 60 C. for an hour to kill the microbes. It is then poured into a vessel containing antiplague serum. The bacilli become agglutinated and fall to the bottom in twelve hours. The supernatant fluid is decanted and the clumped bacilli are thoroughly rinsed and then mixed with "physiologic water." The resulting emulsion is the vaccine to be injected. Cholera and typhoid vaccine are made in the same way except that the anti-serum is added before the microbes are heated. The entire process is complete in a day. The animals injected with the vaccines elaborate specific antibodies. The vaccines retain their immunizing properties a long time. By Haffkine's method the immunization obtained is durable but does not commence until the eighth to twelfth day, while the immunization obtained with prepared serum is rapid and harmless, but vanishes by the eighth to the fifteenth day.

65. Surgery of the Arteries.—Jaboulay reports the case of a healthy young butcher who accidentally cut the femoral artery just above the thigh. As the arteries were in such good condition Jaboulay treated the case by tying the femoral artery above and below the wound and also a collateral near by. There was no general reaction, and after six days the only trace of the intervention was the absence of the pulse at the usual points in the leg. The elastic and supple tissues promptly adapted themselves to the new arrangement. In another patient, a man of 47, with alcoholic antecedents, intermittent claudication and pain in the right leg were the early signs of defective circulation which progressed to gangrene of the limb requiring amputation first at the knee and then at the hip. The same symptoms commenced to develop in the other leg, and he was treated by making an anastomosis between the femoral artery and vein, which has been done twice by A. San Martin of Madrid, as he published last year. Jaboulay performed the operation as in an intestinal anastomosis, but was obliged to apply a central ligature on each vessel while suturing. This ligature evidently had an injurious effect as the circulation was not re-established as hoped, and the local temperature progressively declined. The condition was evidently worse than before. The patient refused further intervention, but it might have been possible to improve matters by severing the external iliac and implanting it in the corresponding portion of the adjacent vein, with an end-to-end suture. Jaboulay's assistant, Carrel, has successfully anastomosed the carotid artery and jugular vein in dogs, and Jaboulay thinks that this operation may yet prove of service in cases of insufficient arterial irrigation of the brain from thrombosis or congenital defective development. Softening of the brain, ischemia and microcephalic idiocy should be the first to reap the advantage of this operation, which bofrows from the veins the route for the transportation of oxygenated blood. We know that arterio-venous aneurysms of the common carotid do not entail cerebral dis-

turbances, and we also know that venous stasis favors the development of a limb. An Esmarch bandage applied in a way to hinder only the return of the venous blood, leads in time to the hypertrophy of the member. It is, therefore, possible that an afflux of arterial blood in the veins of the neck and brain might arouse or augment the vitality of the latter. There need be no fear of venous stasis in the hemisphere corresponding to the anastomosis, as the communications between the veins of the two hemispheres and the extracranial veins are amply developed and ensure the return of the venous blood. We also have learned that ligature of the jugular vein does not entail edema of the brain nor any cerebral troubles. The first results of experimental research in this new field have been very encouraging.

77. **Internal Treatment of Biliary Lithiasis.**—Aldor energetically condemns the usual method of watering-place treatment of gallstones, drinking the water and taking long walks, etc. He emphasizes the necessity of recognizing that the trouble is of infectious nature and that the resulting inflammation requires absolute rest to favor its healing, which is the essence of the cure. The behavior of the stones is a secondary matter. He orders his patient to stay in bed and has cataplasms as hot as he can bear applied to the region of the gallbladder from 7 to 12 a. m. and from 2 to 7 p. m. Every two hours the patient must drink from 100 to 200 c.c. of Carlsbad "Sprudel" at 50 to 55 C., thus ingesting in the course of the day 700 c.c. to 1.5 quarts, beginning at 7 a. m. and continuing until 7 p. m. He must have a mixed diet, as abundant as possible, with nothing tabooed except highly-seasoned and irritating dishes. This treatment must be maintained until the disappearance of the last trace of pain and sensitiveness to pressure. A complete cure is generally attained in four or five weeks and only rarely was it necessary to continue it to the eighth or tenth week; still rarer the cases in which an operation proved necessary after all. A course of Carlsbad waters does not necessarily mean at Carlsbad, but it must be carried out along these lines to be successful. He does not attribute any magic stone-dissolving or stone-expelling virtue to the waters but merely counts on their long-established efficacy in subduing inflammation in the biliary passages.

88. **Surgery in the Tropics.**—Ziemann reports an instance of the remarkable way in which wounds heal at Cameroon. The patient was a primipara of 36, the wife of a missionary in a remote hamlet, tended only by an obstetric nurse, also a missionary. When Cesarean section became necessary as a last resort, the midwife shrank from attempting a longitudinal incision and cut across, 2 cm. below the umbilicus, making a transverse incision 16 cm. long, without chloroform or proper instruments, but with careful asepsis. A healthy boy was delivered and the mother made a smooth recovery. No attempt was made to suture the uterus.

112. Spindle-Shaped Dilatation of Lower Portion of Esophagus.—Zusch has observed 11 cases of this affection and reviews 13 in the literature. He treats it by emptying the sac and rinsing the esophagus every morning before breakfast, feeding exclusively through a wide tube three times a day. He gradually intersperses between these meals a small amount of soft foods from time to time until able to abandon the tube feeding altogether. It is necessary to introduce the tube before bedtime so that no food may stagnate in the sac during the night. In rinsing the esophagus the amount of water used must be small in order not to distend the sac. Frequent sipping of some alkaline water during the day is the best means of alleviating catarrhal inflammation, thus neutralizing any acids that may form while keeping the esophagus clean. An important factor in treatment is lavage of the stomach immediately after rinsing the esophagus. Laxatives irritate the sac and should be avoided. In one case the feeding through a tube was kept up for six months, and the sac was reduced from a capacity of 220 to 50 c.c. Systematic perseverance is the main factor in curing the condition and the patients must learn to introduce the tube themselves. It usually stops as it reaches the cardia, but by swallowing and slight manual coaxing, it slides into the stomach. In case of a tendency to spasmodic contraction the patient should eat solids first and his soup last. Another important precaution is to take considerable butter at supper or a teaspoonful of olive oil. None of his patients would consent to an operation, but it should be borne prominently in mind. In seven typical cases the diagnosis was based on the characteristic anamnesis and subjective sensations, on the evidence of a cavity above the stomach whose contents differed both physically and chemically from those of the stomach, on the tapering of the cavity at top and bottom, and on the exclusion of cardiac stenosis. The tube could always be passed readily into the stomach.

126. Determination of Venous Pressure in Heart Disease.—Frey emphasizes the necessity of surveillance over the circulation as a means of determining proper dosage for the diet, for exercise and carbonated baths. The pressure should be noted before and after each single procedure. The measurement of the venous pressure will be found especially instructive in this respect. It not only enables us to watch the progress of the case, but, correctly interpreted, it may protect the patient and the physician from the most painful surprises.

127. Phosphorus in Osteomalacia.—His administered an oil solution of phosphorus in a case distinguished by numerous spontaneous fractures. The lime eliminated by the patient was calculated before, during and after the phosphorus treatment, and showed that there was a surplus eliminated of .07 to .17 gm. of lime a day ordinarily, but under the influence of the phosphorus there was retention of .301 gm. a day.

133. Serum from Convalescents in Treating Scarlet Fever.—The disease was apparently abbreviated to a notable extent in the 16 cases of scarlet fever which Von Leyden treated with 10 to 20 c.c. of serum taken from other patients convalescing from the disease.

150. Tremor and Urinary Intoxication.—Partial retention of urine is frequently not recognized by the subject and yet it is liable to cause serious symptoms from autointoxication. Among the more frequent are disturbances in the digestive tract, severe constipation, rebellious diarrheas, uncontrollable vomiting, cured at one stroke by removal of the obstacle to free evacuation of urine. Other symptoms observed are migraine, singultus accompanying cystitis, psychoses, etc., and Pawinsky has reported 5 cases of severe "vesical asthma," as he calls it. In the case described by Hock an intense tremor of the entire body, very annoying and assumed to be senile tremor, vanished completely as measures were taken to secure the complete evacuation of urine.

151. Operative Treatment of Ectopia Testis Congenita.—The aim of Katzenstein's operation is to fasten the testicle in its normal position until the cord has stretched and the nourishment is fully assured. He accomplished this in a case in which the atrophic scrotum offered no firm support, by bringing the testicle down into place by means of forceps passed up through an incision at the bottom of the scrotum. A pedunculated skin flap was then cut in the inner aspect of the thigh in contact with the scrotum and sutured to the newly brought down testicle, the raw side in. This not only holds the testicle firmly in its normal position but ensures abundant nourishment.

152. Syphilis Bacillus.—Joseph and Piorkowski announce that they have found a special bacillus in the semen of 39 syphilitics. They never found it in subjects who no longer exhibited any manifestations of the syphilis. Fifteen such cases were examined. In one case symptoms of syphilis continued to recur, notwithstanding energetic and repeated mercurial treatment. When examined for the bacilli a number of years after the primary infection they were found, but not so numerous nor so vigorous as in the others. In another case in which manifestations of the syphilis undoubtedly existed but in which wife and children had not been infected, the sperma and also the secretions of an ulcerative syphilid were constantly sterile. In 24 cases they were able to cultivate the bacillus from the secretions of ulcera dura, but never from ulcera mollia or other non-syphilitic lesions. Mercurial treatment banishes the bacillus from the secretions even years after the primary infection, and on the other hand it could frequently be found two months to several years after infection in the absence of specific treatment. If experience confirms these findings it may be possible to determine by the presence or absence of these

bacilli whether the subject should be allowed to marry or not. The bacilli differ from others in several particulars. They are non-motile, not acid proof, and grow on blood serum in isolated colonies like drops of dew. They form indol but not gas and develop within twenty-four to forty-eight hours, taking the Gram, the poles staining. Inoculation of animals has been negative or dubious.

154. **Hypertrophy of Heart in Kidney Disease.**—Senator cites evidence which establishes the tendency of the heart to hypertrophy in case of kidney disease, and its predominance in the left ventricle. He then suggests as an explanation of this fact that the nitrogenized extractives which are retained in the body by the deficient elimination through the kidneys, alter the composition of the blood and this in turn has an injurious action on the entire vascular system. In acute nephritis this retention is most pronounced, and the vessels suffer intensely from it; their nourishment is impaired and they become more permeable, allowing the passage of fluid through their walls and consequent dropsical effusions. This tendency to dropsy can be regarded as a compensatory phenomenon, an effort to free the blood from the extractives. They are found in the effusions in the same proportions as in the blood. As the kidneys recover from the acute nephritis conditions in the vascular system return to normal and the affection does not last long enough for the heart to be permanently affected. In subchronic nephritis the conditions are the same, except that they occur more gradually, and the vascular system feels the effect longer. The walls of the vessels become contracted, the muscularis thicker and shows the effect of inflammatory induration. This is especially liable to occur in the systemic circulation, which is further injured by direct pressure of dropsical effusions on certain vessels. This degeneration of the vessel walls entails exaggerated work on the left ventricle, which becomes hypertrophied in consequence. In chronic interstitial nephritis the morbid process in the kidney develops so gradually that the walls of the vessels are not injured to the point of becoming permeable and the extractives accumulate in larger and larger amounts in the blood. This slow, but ever-increasing irritation for the vessel walls causes their contraction and thickening in the systemic circulation and compels the entire heart to become hypertrophied while the left ventricle feels the effect more than the rest. It is possible that the noxious influence responsible for the kidney affection may also act simultaneously on the vascular system, as in chronic lead poisoning, arteriosclerosis, etc. In arteriosclerosis the left ventricle is peculiarly liable to suffer in case of sclerosis of the splanchnic arteries.

155. **Surgery of the Ureter.**—Israel had a patient with a solitary hydronephrotic kidney with one ureter completely and the other partially obstructed. The urine escaped through a fistula, and attempts to close it caused distension of the kidney owing to the imperfect drainage. He made a suprapubic opening into the bladder and inserted a rubber tube drain with broad lip in each of the fistulas, connecting the two drains with a rubber tube. The urine thus flows out of the kidney through the renal fistula and into the bladder through the suprapubic fistula, whence it is normally voided. He gives a cut of the connecting tube which has a special valve arrangement. The contrivance is satisfactory and the patient is dry and continent. He also describes two cases of implantation of the ureter in the bladder by an extraperitoneal operation. One patient operated on in 1898 has been permanently cured of all disturbance and he has since had another successful case.

156. **Suture of Perineum.**—Zweifel remarks that he has never witnessed a case of spontaneous healing even after a laceration of the first and second degree. The coating over of the outer skin is not actual healing when there is a gap beneath. In 25 cases of laceration of the third degree observed at the Leipsic Clinic, 20 different physicians had sutured the wound in 20 different cases, and the result had been a failure. In the Maternity 23 cases had occurred and suture was unsuccessful in 6, although the conditions in the hospital are incomparably more favorable than with a physician alone in a private house. Lacerations of the third degree occurred once in each 500 births at the clinic; lacerations of the other degrees thirty-seven times. The successful results of suture of those of the first and second degrees show that physicians are able to secure primary union. In the damage suit mentioned in the title of the communication, Zweifel testified to the above effect and the defendant was acquitted, particularly as he had notified a specialist that the patient needed the attention of an expert. Zweifel attributes the lack of success in most cases to the conditions at the first defecation. When the bowels are filled with scybalæ, accumulated by the frequently morbidly exaggerated appetite of the pregnant woman, the first evacuation is liable to burst the suture of the laceration and render the condition worse than at first. For this reason he advises administering magnesia or something of the kind to soften the fecal masses, and to clear out the lower bowel by introducing a large tube and allowing water to flow in and be constantly siphoned out again. The food should be exclusively fluid. The first step in the suture should be to insert a thread with long ends at each end of each side of the tear. This enables the lips of the wound to be coaptated. He then passes a row of sunken interrupted sutures through the recto-vaginal wall, from within outward, avoiding passing through the mucosa of the rectum. The vaginal portion of the laceration is next sutured in the same way, commencing at the inner angle. The central portion of the laceration is then sutured in the depths with a continuous catgut suture, not to leave any dead space, and the skin sutured above. He recommends catgut for the vaginal sutures and the buried running suture, but for the outer one, silkworm gut, silver wire or celluloid thread. Ordinary silk should not be used at all. Cocain should be injected as a preliminary measure, about four syringefuls, under the skin of the perineum four minutes before commencing to suture, which should not be delayed more than twenty-four hours after delivery. The intervention has thus six steps. 1, the cocain; 2, the "bridle" threads at the corners of the wound; 3, interrupted sutures coaptating the mucosa of the rectum without passing through it; 4, a row of sutures uniting the vaginal portion of the tear; 5, a continuous deep buried suture uniting the depths of the wound, and 6, the silkworm-gut suture of the perineum. Zweifel admits that he does not follow this technic himself in all particulars, but has thus simplified it for the general practitioner. The various steps are illustrated and he urges that no one should allow a laceration to go unoperated at the proper time.

157. **Biologic Extra Work in Artificial Infant Feeding.**—Wassermann, by means of the precipitation of albumin and other applications of the specific precipitation with prepared sera, has established that the albumin in cow's milk has to be elaborated by the infant organism before it can be assimilated like the albumin in human milk. This imposes on the infant organism as much of a task as if a workman, instead of being given steel with which to make a certain machine were given iron which he had to make into steel before he could commence on his task proper. He states that the nourishment of the infant by the mother's milk is merely a continuation and slight modification of the intrauterine nourishment of the fetus through the placenta. The essential albumin required is supplied in this form from the maternal organism, until the infant is old enough to dispense with it. The biologic extra work of the bottle baby is most excessive during the earliest weeks and months of its life. As lactation wanes, the bottle-fed and the breast baby approach the same plane.

164. **Treatment of Lupus Under a Vacuum.**—Meldola refers to the fact that absorption of fluids proceeds much more energetically in a vacuum, and states that he has applied this principle to the treatment of lupus with fine results. He uses the Gould apparatus, which produces a partial local vacuum while allowing the introduction of a fluid. He applied in this way a 50 to 70 per cent. solution of lactic acid with a vacuum over the part treated. Slight inflammation follows, but is transient, and no reaction occurs after the first application.

174. **Method of Sterilizing Catgut.**—Claudius describes the method of sterilizing catgut in use at Bloch's Clinic in Copenhagen, with constantly-increasing satisfaction. Ordinary raw catgut is wound on a glass spool, two knotted threads to a spool, and placed in an aqueous solution of iodin 1 part, potassium iodid 1 part and 100 parts water. The potassium iodid is first dissolved in a small amount of water, and then the finely-pulverized iodin added and dissolved in the same, after which this concentrated solution is diluted to 1 per cent. The glass jar is labeled with the date and after eight days the catgut is ready to use and is kept indefinitely in the same jar and fluid. When wanted, a spool is removed to a dish containing a 3 per cent. solution of carbolic acid or any indifferent sterile fluid. It is left in this fluid for one and a half to two hours, no longer, to rinse off the superfluous iodin solution. The threads are then cut below the surface of the fluid, and any not needed is replaced in the iodin jar. The catgut acquires a peculiar consistency by this method of sterilization, plastic and elastic, like that of a fine copper wire, and it is easy to tie. The strength is increased by the carbolized rinsing while the length is not altered. Tests showed that all spores are killed long before the eight days have elapsed. He states that none of the qualities of the catgut are impaired by even as long as five months in the fluid as he has established again and again.

189. **Parenchymatous Nephritis in Syphilis.**—Wagner describes 3 and reviews 11 cases in the literature, in which there was an unmistakable direct connection between the syphilitic infection and the nephritis and no other cause for the latter could be ascertained. In differentiating the affection a concomitant gonorrhea must be excluded, likewise the ordinary causes of nephritis, or a preceding affection of the kidneys, which may have run a latent course and been roused to an exacerbation by energetic mercurial treatment. In the 14 cases referred to the syphilis was inherited in 4, and the others were all, with one exception, in the secondary stage of syphilis. The nephritis developed simultaneously with or shortly after the appearance of the first secondary symptoms, and this coincidence is one of the most important points in the differentiation. The symptoms and course are about the same as in an ordinary parenchymatous nephritis. Five cases terminated fatally, one from an intercurrent affection and 4 from the results of the nephritis. Recovery was complete in 8 cases, both from the nephritis and the syphilis, as has been determined by observation extending over a number of years. Even in these favorable cases the onset was severe, the albuminuria intense and the anasarca profuse. Symptoms of uremia were noted in three cases, but of brief duration. The nephritis, therefore, may commence stormily and may prove fatal or may terminate in complete recovery, notwithstanding a tempestuous onset. The pathologic anatomy does not differ from that ordinarily observed. Opinions differ in regard to the practicability of instituting specific treatment. Specialists in syphilis advocate it while the internists point out the dangers. Senator is one of those who recommend only potassium iodid and not mercury, as he has witnessed aggravations of the nephritis follow mercurial treatment as frequently as improvement. In the 14 cases reviewed, 3 received no mercury, and 2 of these patients died with symptoms of uremia. In the third case, as the nephritis did not improve under potassium iodid, Zittmann's decoction was then given and the patient recovered. All the other patients were treated with mercury combined with the iodid, and in only one instance was any injurious effect of the mercury noted. In this case inunctions were energetically applied in the beginning of the syphilis and in its recurrences with no evil effects on the kidneys, but after the nephritis developed, an attempt to repeat the inunctions aggravated the kidney affection and mercurial treatment had to be abandoned. In none of the other 8 cases were any symptoms of injury of the kidneys observed. On the contrary, the nephritis subsided completely and permanently. These facts that 3 died out of the 4 not receiving mercurial treatment, while 8 recovered out of the 10 who were given courses of mercury, amply justify specific treatment in syphilitic parenchymatous nephritis. The first stormy onset should be allowed to subside under the ordinary dietetic-hygienic treatment before instituting it, and the doses should be small at first, carefully supervised and interrupted at the first signs of injury to the kidneys. Curschmann and others warn explicitly against injecting the mercury —cautious inunctions are the only means of applying it.

190. **Connection Between Tonsillitis and Appendicitis.**—Weber assumes a causal connection between the tonsillitis and the appendicitis in three cases he describes, although as the patients recovered without an operation it was impossible to determine the identity of the germ causing the affection at the two points. Kretz and Schnitzler found the streptococcus in both tonsils and appendix in their cases, and Adrians the influenza bacillus. Weber agrees with Kretz that the most probable means of infection is the swallowing of germs from the process in the throat and their lodgment in the appendix. In his cases the appendicitis developed seven days after recovery from the acute tonsillitis in one case, during its course in another and in the third both affections were present when the patient was first seen.

191. **Pawlow's Research on Innervation of the Digestion.**—Cohnheim spent his vacation inspecting Pawlow's famous laboratory entirely devoted to research on the mechanism of digestion. It is a small building in the outskirts of St. Petersburg, lavishly endowed, and here also Nencki conducted his studies in physiologic chemistry. Pawlow's work is done exclusively on large dogs weighing from 25 to 30 kilos., 60 pounds and over. He has forty-three in the establishment, all lively and healthy, but each with one or more fistulæ of various kinds. The "psychic gastric juice" is secreted by dogs with a fistula into the stomach and another in the throat. When the stomach is mechanically stimulated through the gastric fistula there is no response in secretion, but after the animal is given a piece of meat the stomach commences to secrete. The dog eats, chews and swallows the meat but it falls out through the hole in the esophagus and he picks it up and eats it over and over

again. After 5.5 minutes have elapsed the gastric juice begins to stream out of the stomach fistula although no food has passed into the stomach. Four dogs thus produce six to eight quarts of gastric juice during the morning, each about 5 to 15 c.c. a minute. They generally cease eating in about twenty minutes, but one dog continued the entire forenoon to eat the same piece of meat over and over again. The gastric juice thus produced is in demand for therapeutic purposes. It contains .5 to .6 per cent. hydrochloric acid and is purer than any gastric juice hitherto attainable. The innervation of the stomach is studied in dogs which have had a second small stomach formed out of the fundus portion, completely separated from the rest except in its innervation. The gastric juice derived from this second stomach differs in amount and in its ferments with the kind of food eaten, which fact is also observed in the "psychic gastric juice" secretion. Since Pawlow's previous publications he has been conducting research on the secretion after an acute gastric catarrh has been induced by application of heat or cold. The mucosa in this case secretes an alkaline mucus instead of the acid gastric juice. After the catarrh has subsided a period of hypoacidity is followed by hyperacidity before normal conditions are restored. In some cases an irritable state ensued, in which the secretion increased and also ceased sooner than normally, an excess of gastric juice being secreted at first, but the total amount below the average. In some of the dogs the psychic secretion was normal, while the chemical was deficient. This demonstrated that the glands were normal while the "reception organ" of the stomach epithelium was affected. Pawlow's research on the pancreatic juice has not fully confirmed his previous announcements on the subject, but it has established that this juice does not contain trypsin as such but in the form of zymogen. This zymogen is transformed into trypsin by the substance in the intestinal juice which he calls enterokinase. This enterokinase is not a constant constituent of the intestinal juice, but is secreted only when the pancreatic juice enters the intestines, evidently a specific chemo-reflex. The fat-splitting ferment becomes active in the same way under the influence of the bile. The pancreatic juice always contains ptyalin and steapsin in this form, but the trypsin occurs in the form of zymogen only when the dogs are fed on bread, milk or potatoes, while on an all-meat diet it occurs as the complete ferment, and on a mixed diet sometimes as one and then as the other. The aim of gastric digestion is to provide the stimulus for the pancreatic secretion, which is the contact of the hydrochloric acid with the mucosa of the intestine. He is still at work on the problem whether this is a reflex or material phenomenon. In his studies on the bile he sutured the orifice of the bile duct with a ring of encircling intestine in the cutaneous wound and has thus been able to study the reflex connection between the intestine and biliary system. He was unable to discover any "psychic" secretion of bile, or any influence of the hydrochloric acid on this secretion. Two substances alone influence it, peptone and fat, as they enter the duodenum. The entrance of fat into the duodenum is the normal stimulus to the secretion of bile. He announced in his published works that the simultaneous ingestion of fat and albumin retarded the secretion of gastric juice. This fact has been confirmed by later research, but he assumed at first that the fat in contact with the gastric mucosa inhibited the secretion. He has since learned that the inhibition is a reflex phenomenon which occurs when the fat comes in contact with the mucosa of the duodenum. The motor function of the stomach is also affected in the same way. If water or a solution of salt, sugar or peptone be introduced into the duodenum through a fistula, and at the same time 200 c.c. of water be poured into the stomach, the latter empties itself in less than fifteen minutes. But if, instead, an acid or fat be introduced into the duodenum, the chemo-reflex closes the pylorus and the water is still found in the stomach two hours later. The experiments also prove that exact experimental physiologic psychology can be studied on dogs. In research on the secretion of saliva, for instance, Pawlow found that dogs with a saliva fistula secreted thin saliva when such was needed to dilute acid or irritating substances taken in the mouth, while they secreted a mucilaginous saliva when needed to lubricate solid pieces of food. If hydrochloric acid was poured into the mouth of a dog, large amounts of the thin saliva were secreted at once. If the acid were stained black, the animal soon learned to recognize it, and on the mere sight of any black fluid the dog commenced to secrete the thin saliva in abundance. Thick saliva is secreted when the dog is given or even shown dry bread. As dogs have the habit of licking their sores, the saliva secretion commences as soon as a slight wound is inflicted on them. In fact, if the Paquelin were merely shown to the animal saliva would commence to flow, after a few experiences with it, and the slightest cauterization anywhere on the body would be followed by the increased secretion, with one exception. This exception was the top of the head. The dogs can not reach the top of their heads with their tongue, and no saliva secretion followed an injury at this point.

196. **Tuberculosis of the Optic Nerve.**—Michel describes and illustrates the pathologic anatomy of tubercular affections of the trunk of the optic nerve. They have been observed almost exclusively in children, and usually present the clinical aspect of a retrobulbar neuritis.

197. **Dosage of Exercise for Tuberculous Patients.**—Penzoldt argues that in case of doubt it is well to bear in mind that too little exercise in these cases is less injurious than too much. When the rectal temperature of a curable patient reaches or surpasses 38 C. he is best treated in bed. The bed can be moved on a veranda, and he therefore advises that all the bedrooms in sanatoriums should open on verandas. The bed rest must be as absolute as in case of typhoid fever. In all cases after acute onset or exacerbations of the tuberculous process the curable patients should avoid all unnecessary movements for an average of two months, even when the disease has seemed to become stationary. The patients should refrain from going up or down stairs, billiards, sports and even walks, except a very slow stroll to and fro. Much harm is done by the getting ready to go to a sanatorium, packing the trunk, etc. The patient should travel with a companion to carry all hand baggage and see that all arrangements are made as for a very sick person. Unless great care be used, the trip to the sanatorium is liable to induce an exacerbation that is responsible for the failure of treatment, and the fatal termination of otherwise curable cases. In determining the effect of exercise in the individual case, it is possible that much information may be derived from the pulse tested during, not after, the exercise and also from the respiration noted without attracting the patient's attention, possibly while taking the pulse. The temperature should always be taken deep in the rectum, and he urges that this method should supplant mouth temperature in all sanatoriums. When after a walk of fifteen to thirty minutes the rectal temperature is 37.8-9 C. (100 F.) it is suspicious, and 38 C. or over is a certain sign that the exercise was too vigorous. The temperature must be taken immediately after the end of the exercise, without any interval. A temperature of 37.8 C. is frequently noted in out-patients without the least trace of tuberculosis. The standard temperature in the evening after complete repose may be accepted as 37.5 C. Consequently tuberculous patients with this "repose temperature" or higher should be warned against unnecessary exercise. It should not be allowed until with material improvement in the general health the temperature does not rise higher with cautiously-attempted movements.

198. **Etiology of Noma.**—The assertions of Perthes in regard to the discovery of a mycelium in cases of noma have been confirmed by Sieffert and Von Ranke now presents illustrations of another case in which the thread fungi were prominently present.

199. **Schleich Narcosis.**—The Schleich Mixture No. 1 was used by Von Winckel in 100 cases and all the particulars carefully tabulated. They show that the time required and the amount of the anesthetic were less than in the narcoses with ether, but that threatening by-effects occurred more frequently and were more serious than with the ether.

Books Received.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review, as dictated by their merits, or in the interests of our readers.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Articles on Medicine, Neurology, Surgery, Therapeutics, Obstetrics, Pediatrics, Pathology, Dermatology, Diseases of the Ear, Eye, Nose and Throat, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession Throughout the World. Edited by Henry W. Cattell, A.M., M.D., Philadelphia, with the Collaboration of John B. Murphy, M.D., Chicago, Alexander D. Blackader, M.D., Montreal, H. C. Wood, M.D., Philadelphia, T. M. Rotch, M.D., Boston, E. Landolt, M.D., Paris, Thomas G. Morton, M.D., Philadelphia, James J. Walsh, M.D., New York, J. W. Ballantyne, M.D., Edinburgh, and John Harold, M.D., London, with Regular Correspondents in Montreal, London, Paris, Leipsic, and Vienna. Volume IV. Twelfth Series, 1903. Cloth. Pp. 317. Price, $2.00. Philadelphia: J. B. Lippincott Co. 1903.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS, or the Action of Drugs in Health and Disease. By Arthur R. Cushny, M.A., M.D., Aberd., Professor of Materia Medica and Therapeutics in the University of Michigan. Third Edition, Revised and Enlarged. Illustrated with 52 Engravings. Cloth. Pp. 756. Price, $3.75. Philadelphia and New York: Lea Brothers & Co.

RECENT ELECTRO-THERAPEUTIC WORK IN MEDICINE AND SURGERY. By John MacIntyre, M.B., F.R.S.E., F.R.M.S., M.I.E.E., Surgeon for Diseases of the Nose and Throat, Glasgow Royal Infirmary. Reprinted from the *Glasgow Medical Journal* for August, 1902. Cloth. Glasgow: Alex. MacDougall. 1902.

MEDICAL AND SURGICAL REPORTS OF THE BOSTON CITY HOSPITAL. Thirteenth Series. Edited by H. L. Burrell, M.D., W. T. Councilman, M.D., and Charles F. Withington, M.D. Paper. Pp. 205. Boston: Published by the Trustees. 1902.

REPORT OF THE TERRITORIAL BOARD OF HEALTH FOR OKLAHOMA. E. E. Cowdrick, Superintendent, Enid, Oklahoma. Paper. Pp. 84. Guthrie, Okla.: State Capital Co. 1902.

The Public Service.

Army Changes.

Movements of Officers of the Medical Department, U. S. Army, under orders from the Adjutant-General's Office, Washington, D. C., from Jan. 19 to 24, 1903:

Branch, Frederick D., contract surgeon, U. S. A., now at East Springfield, N. Y., will proceed to Columbia Arsenal, Tenn., and report in person to the commanding officer thereof for duty, and by letter to the commanding general, Department of the Lakes.

Stone, John H., captain and asst.-surgeon, U. S. A., is detailed as a member of the examining board convened at Fort Leavenworth, Kan., vice First Lieut. David Baker, asst.-surgeon, hereby relieved.

Navy Changes.

Changes in the Medical Corps of the Navy, for the week of January 24:

Drs. G. H. Hart, A. W. Kaines, T. C. Foster, W. H. Block and J. R. Dykes, appointed acting assistant-surgeons.

Surgeon W. F. Arnold, detached from Cavite Naval Station and ordered to Port Isabela, P. I.

Asst.-Surgeon C. M. Oman, detached from Port Isabela, and ordered to the *Frolic*.

P. A. Surgeon A. G. Grunwell, detached from the Naval Hospital, Norfolk, Va., and ordered to the Naval Hospital, Washington, D. C.

P. A. Surgeon N. O. Huntington, detached from the Navy Yard, New York, and ordered to the *Maine*.

P. A. Surgeon D. B. Kerr, detached from recruiting duty and ordered to the *Wabash*.

P. A. Surgeon R. C. Holcomb, commissioned passed assistant-surgeon.

Asst.-Surgeon C. H. DeLancy, detached from recruiting duty, and ordered to the Naval Hospital, Norfolk, Va.

Asst.-Surgeon F. M. Bogan, detached from Naval Hospital, Washington, D. C., and ordered to the Navy Yard, Washington.

Dr. J. P. DeBruler, appointed assistant-surgeon, Jan. 3, 1903.

A. A. Surgeons R. A. Campbell, W. P. Keene and R. B. Chapman, ordered to duty with recruiting party.

P. A. Surgeon R. W. Plummer, detached from recruiting duty and ordered to the *Prairie*.

P. A. Surgeon F. M. Furlong, detached from recruiting duty and ordered to the Navy Yard, New York.

A. A. Surgeon J. T. Miller, ordered to recruiting duty.

A. A. Surgeon W. H. Janney, ordered to the Naval Hospital, Port Royal, S. C.

Surgeon A. M. Moore, retired, appointed member of board of examiners, civil engineers, Chicago.

Surgeon J. C. Byrnes, additional duty as member of board, examination of civil engineers, New York.

Surgeon E. M. Blackwell, additional duty as member of board, examination for civil engineers, New York.

Marine-Hospital Changes.

Official list of the changes of station and duties of commissioned and non-commissioned officers of the Public Health and Marine-Hospital Service for the seven days ended Jan. 22, 1903:

Surgeon Preston H. Bailhache, leave of absence for thirty days from January 6, amended so that it shall be for 12 days.

Surgeon H. W. Austin, leave of absence for three days under Paragraph 179 of the regulations.

P. A. Surgeon G. M. Guiteras, granted leave of absence for seven days, under Paragraph 181 of the regulations, from January 19.

P. A. Surgeon J. H. Oakley, leave of absence for two days granted by Bureau letter of January 13 revoked.

Asst.-Surgeon W. A. Korn, to proceed to Delaware Breakwater Quarantine, and assume temporary charge of the station during the absence, on leave of P. A. Surgeon C. H. Lavinder.

Asst.-Surgeon J. S. Boggess, granted leave of absence for four days from January 21.

A. A. Surgeon F. F. Sams, leave of absence for thirty days from January 1, granted by Department letter of January 5, amended to read thirty days from January 5.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended Jan. 4, 1903:

SMALLPOX—UNITED STATES.

California: San Francisco, Dec. 28-Jan 11, 10 cases.
Colorado: Denver, Jan. 3-10, 7 cases.
District of Columbia: Washington, Jan. 10-17, 2 cases.
Illinois: Chicago, Jan. 10-17, 14 cases.
Indiana: Jan. 10-17, Evansville, 3 cases, 2 imported on river steamer; South Bend, 5 cases.
Kansas: Wichita, Jan. 10-17, 1 case.
Kentucky: Lexington, Jan. 10-17, 1 case; Louisville, Jan. 14, 1 case.
Louisiana: New Orleans, Jan. 10-17, 1 case.
Maine: Jan. 10-17, Biddeford, 15 cases; Lewiston, 17 cases.
Massachusetts: Jan. 10-17, Boston, 15 cases, 3 deaths; Cambridge, 1 case; Chelsea, 1 case; Melrose, 1 case.
Michigan: Grand Rapids, Jan. 10-17, 6 cases.
Missouri: St. Louis, Jan. 4-18, 31 cases.
Nebraska: Omaha, Jan. 10-17, 10 cases.
New Hampshire: Nashua, Jan. 10-17, 4 cases.
New Jersey: Jan. 10-17, Camden, 3 cases; Newark, 3 cases, 1 death; Plainfield, 2 cases.
New York: Jan. 10-17, Buffalo, 5 cases; New York, 2 cases, 1 death.
Ohio: Cincinnati, Jan. 2-16, 22 cases; Cleveland, Jan. 10-17, 16 cases; Dayton, Jan. 10-17, 4 cases; Hamilton, Jan. 10-17, 1 case.
Pennsylvania: Jan. 10-17, Altoona, 1 case; Erie, 4 cases, 1 death; Johnstown, 8 cases; McKeesport, 3 cases; Philadelphia, 35 cases, 2 deaths; Pittsburg, 19 cases, 3 deaths.
South Carolina: Charleston, Jan. 3-17, 9 cases.
Tennessee: Memphis, Jan. 10-17, 4 cases.
Texas: San Antonio, Dec. 1-31, 3 cases.
Utah: Salt Lake City, Jan. 3-17, 45 cases, 1 death.
Virginia: Danville, Jan. 10-17, 9 cases, 1 death.
Wisconsin: Green Bay, Jan. 11-18, 1 case; Milwaukee, Jan. 10-17, 13 cases.

SMALLPOX—FOREIGN.

Austria: Prague, Dec. 20-27, 5 cases.
Barbados: Dec. 19-Jan. 2, 9 cases, 1 death.
Belgium: Dec. 20-27, Antwerp, 4 cases, 1 death; Brussels, 2 deaths.
Brazil: Bahia, Dec. 13-27, 4 cases.
Canada: Amherstburg, Jan. 10-17, 2 cases.
Canary Islands: Las Palmas, Dec. 6-13, 2 cases.
Great Britain: Dec. 27-Jan. 3, Birmingham, 2 cases; Leeds, 7 cases; Liverpool, 48 cases, 3 deaths; London, 14 cases; Manchester, 5 cases.
India: Bombay, Dec. 9-23, 10 deaths; Madras, Nov. 27-Dec. 12, 2 deaths.
Italy: Palermo, Dec. 20-27, 13 cases, 1 death.
Mexico: City of Medico, Jan. 4-14, 4 cases, 2 deaths.
Russia: Moscow, Dec. 13-20, 2 cases, 2 deaths; Odessa, Dec. 20-27, 5 cases, 2 deaths; St. Petersburg, Dec. 20-27, 21 cases, 2 deaths.
Straits Settlements: Singapore, Nov. 8-Dec. 6, 12 deaths.

YELLOW FEVER.

Columbia: Panama, Dec. 29-Jan. 12, 9 cases, 3 deaths.
Ecuador: Guayaquil, Dec. 20-Jan. 3, 22 deaths.
Mexico: Tampico, Jan. 3-10, 6 deaths; Vera Cruz, Jan. 3-17, 9 cases, 8 deaths.

CHOLERA—INSULAR.

Philippines: Manila, Nov. 16-Dec. 6, 154 cases, 126 deaths; total to Dec. 9, 4,533 cases and 3,402 deaths. Provinces, Nov. 16-Dec. 6, 1,358 cases, 852 deaths; total to Dec. 9, approximate, 117,246 cases and 74,505 deaths.

CHOLERA—FOREIGN.

Egypt: Alexandria, Dec. 12-26, 21 cases, 16 deaths.
India: Bombay, Dec. 9-23, 3 deaths; Calcutta, Dec. 6-13, 35 deaths.

PLAGUE—INSULAR.

Hawaii: Honolulu, Dec. 31, 1 death.

PLAGUE—FOREIGN.

India: Bombay, Dec. 8-23, 243 deaths; Calcutta. Dec. 6-13, 18 deaths; Karachi, Dec. 7-14, 17 cases, 14 deaths.

GUNSHOT WOUNDS OF THE THORAX AND ABDOMEN.

FROM THE VIEWPOINT OF THE CIVIL SURGEON.*

W. L. RODMAN, M.D.

PHILADELPHIA.

INTRODUCTION.

In a fifteen-minute paper it will be only possible for me to deal with a few of the most important principles involving the diagnosis, prognosis and treatment of gunshot wounds of the thorax and abdomen. They must, moreover, be treated in a general way, as extended consideration of the injuries possible to each organ or viscus is clearly out of the question. I shall largely avoid statistics, as they are unsatisfactory unless the size and character of the missile, its range and velocity, the probable condition of the viscus at the time of the injury, and the length of time supervening before the surgeon sees the case, are given. I shall also avoid all theories as to ballistics and the resistance of the different tissues as demonstrated by experimentation, leaving such matters to my good friend and distinguished confrère, Major LaGarde. I shall take the cases as we see them on the streets, in their home or in hospitals.

GUNSHOT WOUNDS OF THE THORAX. 1. CHARACTER.

Shot wounds of the thorax are penetrating or nonpenetrating, the former when the cavity is opened, the latter when there is only a superficial wound of the soft parts. The latter class may at once be dismissed as being of little more importance than other flesh wounds, the only difference being that shock is necessarily greater, and in a few cases very much more pronounced. I have known the wind knocked out of a man primarily, and marked shock caused secondarily, by a superficial pistol shot wound. Slight hemoptysis may also occur from concussion, and is not pathognomonic, as has been taught, of penetration.

Penetrating wounds may involve pleuræ, lungs and bronchi, or any tissue in the anterior, middle or posterior mediastinum, as pericardium, heart and great vessels, thoracic duct, esophagus, or indeed anything contained in the theoracic cavity. I have never known a bullet to injure the esophagus or other tissues placed in the posterior mediastinum, and it is remarkable how few such cases are recorded even by military surgeons, when we consider the great number of chest injuries received in battle. The number thus wounded in street fights also is large, for in an altercation where pistols are used as weapons at close range, the chest is usually aimed at. I should say, in a reasonably large experience with gunshot injuries, there have been ten times as many of the thorax as the abdomen.

2. DIAGNOSIS.

The diagnosis of penetration is, as a rule, not difficult, and should always be made without the use of a probe, as it is as harmful in thoracic as in abdominal wounds. The lungs, for manifest reasons, will suffer far more frequently than all other thoracic viscera, and the diagnosis of penetrating chest injuries is largely the diagnosis of wounds of the lung.

Injuries of the heart and great vessels are so quickly fatal that less interest attaches to their diagnosis. They are not invariably fatal, however, as many supposed before the days of the *x*-rays. Bullets have been located in the substance of the heart sometime after complete recovery. If the cavities of the heart are opened, death nearly always ensues. The diagnosis of penetrating wounds of the lung is to be made by shock; hemoptysis; external hemorrhage, which is rarely great, and when present is practically always due to a wound of an intercostal vessel by a ball of large caliber; by emphysema, local or general, or both. In balls of small caliber, as a 32, or those of lesser size, it is surprising how few symptoms may be present.

I have known a young wife, suffering from post-marital insanity, to fire two pistol balls, 32 caliber, through her lung in the region of the heart and present no symptoms beyond a slight hemoptysis when I saw her, three hours afterward. Her recovery was uneventful.

The amount of external hemorrhage in such cases is nearly always less than one would suppose from the vascularity of the pulmonary tissues. But other elements to reckon with are elasticity and slight resistance. Hemothorax, which sooner or later may be the most pronounced sign of a penetrating wound of the lung, is nearly always due to injury of an intercostal vessel, and is therefore from a parietal and not a visceral source. This is important to remember in the treatment of such injuries.

3. PROGNOSIS.

I wish to say most emphatically that my own experience leads me to reject absolutely the teaching of most of our standard text-books on surgery, and to accept that of modern military surgeons, which is exactly the opposite, and correct. Shot wounds of the chest, as we see them in civil life, either die at once from shock and hemorrhage or, very generally, get well. Later dangers as hemothorax, pyothorax, pleurisy, pneumonia

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Surgery and Anatomy, and approved for publication by the Executive Committee: Drs. H. O. Walker, A. J. Ochsner and DeForest Willard.

and abscess, are exceptional, and usually due to meddlesome surgery. Probing, either with an instrument or unsterile finger, has been the cause of death in thousands of such cases. Infection may be carried in with a bullet which has adherent to it a piece of skin or clothing, but such cases are, I repeat, exceptional. Thoracic wounds occurring in young or middle-aged subjects in good health, if kept from infection, very generally recover. I have treated dozens of such cases shot with pistol balls of caliber from 22 to 44, a few with rifle balls of large caliber, and two from slugs and large shot fired from a shotgun, and have never seen a death that did not occur in a few hours from shock and hemorrhage combined. A few cases, usually large balls in the lung substance, have had stormy convalescences, but a vast majority have had painless and uneventful recoveries.

I now recall the case of Sidney Smith, living near Louisville, Ky., who received two perforating wounds made by a 38-caliber revolver, one through the apex of the right lung, making its exit through the middle of the scapula, the other passing through the left lung just above the heart, lodging beneath the skin over the left scapula. There were no disquieting symptoms, and he actually wanted to leave his bed the following day to renew the difficulty with his assailants, and was only quieted with the information that one of them was *hors de combat* from an abdominal wound, and the other had left the country. I made but two visits to the case, as he lived ten miles from Louisville, and there were no reasons for going more frequently.

I recall another case treated in the Louisville City Hospital, where a burglar was caught entering a store early one Sunday morning and received a charge of slugs and shot in his right lung, fired at close range. An opening was made almost large enough to admit my fist, several ribs being severed into fragments. The house surgeon before my arrival, and I afterward, removed a large number of slugs, shot and clothing from the lacerated lung substance; the ribs were, of course, resected. To my great surprise this man also recovered and did not even suffer from a pyothorax. Free drainage saved him.

4. TREATMENT.

The treatment for shot wounds of the thorax should, as a rule, be a masterly inactivity. The less done the better. The wound should at once be covered with a sterile dressing, that side of the chest immobilized as far as possible, and the patient transported quickly and quietly to his home or a hospital. It is always better to have such cases in a hospital where the *x*-rays can be used if desirable. Hemorrhage, either external or internal, will rarely be great, and when it is, is nearly always due to injury of an intercostal vessel and will be controlled by strapping. Any attempt to ligate the vessel in an emergency case is liable to result in infection, and to be followed by pyothorax, pleurisy, pneumonia or all. I have but once seen free external hemorrhage after a shot wound of the lung.

A negro was caught trespassing on a farm after being warned to keep off, and was shot in the right side with a large rifle ball, which cut the fifth intercostal vessels. When I reached the man he was pulseless, of the peculiar ashy gray color seen in the negro suffering from shock and hemorrhage, the latter particularly, and blood was flowing from the wound in a steady stream, showing that the pleural cavity was partly full of blood; at least up to the level of the wound. The environments were not favorable for ligating the vessel, so I transfixed the wound with a needle, tied a figure-of-eight suture over it, strapped the chest and sent the case to the Louisville City Hospital. I had no doubt this man would die, but he recovered without a pyothorax. A large amount of liquid blood was aspirated a few days afterward, this being all that was necessary.

A study of all the cases of gunshot wounds of the chest during our recent war with Spain, the Anglo-Boer war and the Philippine insurrection will demonstrate the comparative benignity of such wounds, many soldiers again reporting for duty in a very short time. Hemothorax was a frequent complication only in soldiers transported a long distance. Pyothorax occurred only where there was emphysema secondarily. Aspiration, under the strictest aseptic precautions, is to be advised when there is dyspnea or other signs of pressure on the lungs. Absolute rest, cooling drinks, a little opium to control cough, with a sterile immobilizing dressing, constitute the only treatment necessary in the vast majority of cases. In severe hemorrhage saline infusion should, of course, be practiced. Any attempt to recover a lodged ball from the substance of the lung would be fraught with danger, and would rarely be justifiable. Nearly always will it remain a harmless tenant in the lung tissue, always unless it has carried in septic material. Now that bullets are so easily and accurately located by the *x*-rays, it is tempting to go for them at times when it is injudicious to do so. Patients are not only willing, but insist on the removal of the ball. In no other class of lodged balls is it more necessary to remember Abernethy's epigrammatic statement to his class when lecturing on the treatment of lodged missiles. He said: "Sir Ralph Abercrombie received a bullet in his thigh. The surgeons groped, they groped and they groped, and Sir Ralph Abercrombie died."

I am certain that I have seen death follow the removal of bullets that were doing no harm whatsoever, they having become encysted.

GUNSHOT WOUNDS OF THE ABDOMEN. 1. CHARACTER.

These are penetrating and perforating—the former when the peritoneal cavity is opened, and the latter when any contained viscus, its mesentery or the omentum is wounded. This definition, while not free from objection, is generally adopted in text-books and is therefore accepted.

A bullet may enter the neck, thorax, buttock or thigh, to subsequently penetrate the parietal peritoneum and to cause single or multiple wounds of the intestines or other abdominal contents. Douglass reports a case that entered the sacrosciatic foramen, and caused 13 perforations of the intestines.

Of penetrating abdominal wounds a vast majority are also perforating in character, at least 97 per cent. according to Douglass. That undoubted cases of penetration without perforaton, difficult as it is to understand, do occur even with large pistol balls, all must admit, as such cases are reported by Senn, Stimson, Oliver, Hunter McGuire and others.

I have had one such case: A telegraph operator at East Bernstadt, Ky., was shot with a 38-caliber ball, midway between the ensiform-cartilage and umbilicus, the ball cutting the spinal cord and lodging behind the eleventh dorsal vertebra. There were no symptoms whatsoever to indicate wound of either stomach or intestines, and the man was alive, though paralyzed, a year after the injury. He had been fasting for 24 hours and to this fact, perhaps, is to be attributed his escape from early and actual death, only to lead an existence infinitely worse, a living death.

Wounds above the umbilicus, especially antero-posterior ones, are recognized as being less likely to cause perforation. Those below, and especially oblique ones, are far more likely to be perforating in character; whereas those from flank to flank have heretofore been

generally considered as almost certain to cause one or more perforations.

The last statement, almost universally accepted as it has been, must either be modified so as to conform to the experience of military surgeons in recent wars, or to accept their conclusions that multiple perforations when made by reduced caliber bullets at high velocity may repair themselves spontaneously. Mr. Makin believes that the small intestines in some way escape, and thinks such good fortune is usually due to the fact that soldiers in battle have not infrequently been fasting for many hours.

Sir Frederick Treves, the late Sir William MacCormack, and many other British surgeons, as the result of their experience in South Africa, and Senn, Nancrede, Parker and LaGarde, all saw during our war with Spain penetrating wounds that seemed to be perforating ones, recover. A careful investigation of the subject will convince any one that both sides to the controversy are partly right, and that safety and conservatism lie in a middle course.

A larger per cent. of penetrating wounds than now usually admitted (3 per cent.) are non-perforating. Still, admitting this, and doubling or trebling the number, at least 91 per cent. are perforating in character. Of this 91 per cent. 65 per cent. injure the intestines. After all, this is the important fact to remember, for on its appreciation depends the proper treatment of shot wounds of the abdomen.

In general military surgeons contend that the reduced caliber bullet, nickel clad as it is and of high velocity, may produce one or more wounds of the intestines which in their nature are practically incised ones, and that they may heal spontaneously. They do not claim, however, that such a fortunate result will generally occur and that it is wise to expect it; but in emphasizing the possible fact, do, perhaps, hold out too great a hope of its probability. That it rarely occurs in civil practice with a leaden ball, more or less round and of low velocity, there can be no doubt. I have never seen such a case, and, moreover, have never seen a civil surgeon who had.

"Ever" and "never" are words that have no place in surgery, and it is only fair and reasonable to admit the possibility of spontaneous healing in wounds of any hollow viscus. It will occur so rarely in civil practice that it would be the height of folly to expect or assume that it will do so.

Much depends on the size, shape, character and velocity of the bullet; the viscus wounded, and whether or not it was empty at the time of injury, and of almost as great importance, whether it is a more or less fixed organ as the stomach and large intestines, or freely movable as the small intestines. A reasonable number of wounds of the stomach, large intestines, urinary and gall bladders have been reported by different surgeons as having recovered spontaneously.

Other cases of supposed perforating wounds of the small intestines have recovered without operation, and the case of Lange in civil practice and many others in military practice seem unquestionable.

Richard Douglass reports a case with 13 perforations of the small intestines, and although the patient walked without assistance one mile after he was shot, there was no evidence of intestinal contents having escaped at any of the openings 22 hours after injury, when a laparotomy was done. Now, if this can happen, we simply must admit the possibility of spontaneous cure in one or more favorable wounds of the small intestines. Many instances of pathologic perforations caused by gastric and intestinal ulcers have recovered spontaneously, yet they constitute so small a per cent. of such cases that a physician who rested his treatment and hopes on the slim chances of recovery without operation would be in every way recreant to the trust and responsibility placed on him when even the probable diagnosis of perforation is made.

Would any surgeon in this section hesitate to operate on a strangulated hernia because a few undoubted cases have recovered without operation?

2. DIAGNOSIS.

The time at my command is too precious to spend any of it in considering the symptomatology of intraperitoneal injury. There is nothing to add to what has already been said many, many times, and in fact by every one who has written on the subject.

There will rarely be positive evidence of either penetration or perforation. The only safe way to make a diagnosis is to sterilize the wound, enlarge it under cocain, and with the sterile finger follow the track of the ball until a diagnosis of penetration or non-penetration is made certain. Probes should never be used, as they are both misleading and dangerous. The diagnosis of penetration having been made, the probability of perforation must be assumed.

3. PROGNOSIS.

The prognosis of penetrating shot wounds of the abdomen can not be looked on as otherwise than most grave. Some, of course, are more dangerous than others. Wounds of the solid viscera, especially the liver, are less fatal than perforating wounds of the hollow viscera. Of the latter, wounds of the small intestines are the most dangerous.

As already intimated, wounds of the large intestines, especially the cecum, ascending colon and rectum, on account of their more fixed position, are somewhat less fatal. Contrary to what has usually been taught, extraperitoneal wounds of either intestines or bladder are more fatal than intraperitoneal ones. Of this Makin is positive, and he cites numerous cases to prove his position.

The prognosis of wounds of the abdomen above the umbilicus is better in general than that of those below. Douglass insists, and rightfully, that the difference is not so great as many have thought, for while perforations of the hollow viscera are less frequent, the danger of hemorrhage is much greater. To this also may be added concomitant injuries to the pancreas, kidneys, liver and spleen. So, with Douglass, I dissent from the comparatively favorable prognosis usually given of these injuries.

Antero-posterior wounds are on the whole less dangerous than oblique ones, and of all wounds those from flank to flank are the most fatal. Wounds from the back are more fatal than those entering in front, for two reasons: The uncertainty of diagnosis, and the greater difficulty of repairing the injury. Emptiness of a hollow viscus at the time of injury greatly influences the prognosis for the better.

Of penetrating wounds of the abdomen Seigel's statistics show that of 537 cases not subjected to operation 55.2 per cent. were fatal. Of 763 cases subjected to laparotomy 51.6 per cent. were fatal.

Douglass' statistics are both more recent and more encouraging, and do not include cases in Seigel's collec-

tion, as they were all operated on within the past five years, and were collected indiscriminately from literature since 1895. Of 65 cases operated on 44 recovered, 21 died; mortality, 32.3 per cent.

Douglass' personal statistics are much better, as in his last 8 operations there were but two deaths, and both, we may say, were accidental, as one died from leakage at the site of a Murphy button and the other from a mural abscess many days after injury.

H. H. Grant of Louisville has operated six times—three times resecting intestine—with five recoveries.

4. TREATMENT.

Admitting, as we have done, that small wounds of solid viscera frequently get well spontaneously and that perforations of hollow viscera may, though less frequently do so, no one with experience in such injuries will advise opium and a "do-nothing" policy; no greater mistake could be made.

But I am not here to advocate operation, as that is unnecessary, but I do wish to insist on as early a laparotomy as is consistent with the environments and condition of each case. Not an unnecessary moment should be lost in preparing for an aseptic operation.

It is not only an easy task to prove that cases operated on do better than those not operated on, but as easy a one to show that the chances for recovery are directly proportional to the earliness with which operative measures are begun.

Seigel's statistics (763 cases) show a mortality of 15.2 per cent. in cases operated on during the first four hours; it is 44.4 per cent. from 5 to 8 hours after injury; 63.6 per cent. 9 to 12 hours after injury. It is 70 per cent. in those operated on after 12 hours. The reasons for this are manifest. On impact a bullet causes a momentary spasm of the circular fibers, which produces a hernia of the mucous membrane or ectropion. This is immediately followed by intestinal paresis, and both the ectropion and arrested peristalsis have a tendency to prevent extravasation of intestinal contents.

Extravasation will occur sooner or later, and should always be expected. The important question is when does it occur? It may be moments in one case, hours in another, all depending on the size of ball, angle of impact, condition of wounded viscus—elements that can not possibly be reckoned with in the vast majority of instances. Knowing that it must occur sooner or later, owing to circumstances, it should be the endeavor of the surgeon to operate before dangerous, if not fatal, soiling of the peritoneum has occurred.

All surgeons of experience in such cases have realized that extravasation in gross amount has not usually occurred before the intestines are handled in the operation.

Protecting each aperture with gauze as soon as it is encountered should be the first desideratum. All openings should be quickly closed by Lembert sutures, and further secured, if necessary, by omental grafts. Unnecessary time should not be lost in paring the edges, unless it seems that they are devitalized. Fresh hemorrhage is often thus produced and valuable time wasted. In no other class of operations is judicious speed more necessary.

After all openings in the viscera are closed and hemorrhage controlled, the peritoneal cavity should be copiously flushed with warm sterile water. Sepsis and shock are both best combated in this way. Leaving a reasonable amount of sterile water in the cavity has much to commend it. The pretty general practice of using saline infusion during and subsequent to operation has perhaps done more than anything else to improve recent operative results.

It is my belief that drainage should very generally be employed in shot wounds of the abdomen. In wounds high up, in the lesser peritoneal cavity, for instance, posterior drainage should always be employed. It may also be made with advantage in some wounds low down, as shown by the cases of Harte and LeConte. As to the manner of drainage, some prefer gauze drains; others tubes; others, still, use both. In my judgment it matters little how drainage is made, but it should be made.

Early action of the bowels should be insured by beginning with small doses of calomel soon after the patient comes out of ether. This, I think, safer than injecting a saline into the bowel at the time of operation.

When the surgeon first sees a case of shot wound of the abdomen he may find it in profound shock, and the question of an immediate or delayed operation will be pressing. It can not be too strongly insisted on that in nearly all such cases shock is due to internal hemorrhage, and to wait for its subsidence or amelioration is very generally a fatal mistake. Shock emphasizes the necessity of an immediate operation. A saline infusion should be given at once by an assistant and a laparotomy proceeded with.

While insisting and believing that the safety of all cases of shot wounds of the abdomen will be best subserved by as early a laparotomy as is compatible with the environments, it is also my belief that late cases—even those seen in general peritonitis—should be given the benefit of operation.

In November, 1897, I operated on a case fifty-one hours after two wounds of the small intestines had been received, the man having been brought 250 miles, 9 miles of the journey being made in a wagon over a rough country road. The man was in general peritonitis; pulse, 130; temperature, 103; respiration, 36. I frankly told his brother that it was my belief that he would die on the table, and I operated from a sheer sense of duty. The cavity was full of fecal matter and the outlook could not have been less promising. There were two intestinal wounds. To the surprise of all of us he made a slow but satisfactory recovery, and is perfectly well to-day. For ten days he was delirious, difficult to keep in bed and markedly septic. Free sloughing of the external wound occurred, yet it did not result in ventral hernia.

I have also reported a case of perforating typhoid ulcer which was successfully operated on thirty-seven hours after the accident, the child being in marked general peritonitis, with a pulse of 165; temperature, 103½; respiration, 40.

These two cases have taught me a valuable lesson, and I am not inclined to withhold operation even in advanced general peritonitis—however caused—if I can feel the radial pulse.

Before closing I wish to enter a protest against the teaching which has gone out from time to time that every case of shot wound of the abdomen should be operated on regardless of environments and the ability of the operator. Inexperienced and timid men have, from a false sense of duty, been made to operate on such cases when their lack of training, want of assistants and inadequate facilities foretold disaster to their patient. I have no patience with the statement that I have heard made more than once in medical societies that such cases should be operated on in a stable with a pen knife rather than pursue a course of masterly inactivity. Such talk—I will not dignify it by the name of teaching—is absurd, and brings surgery into well-merited disrepute. A trained abdominal

surgeon should always be had if possible, and it is better to wait a few hours for such an operator than to have an immediate operation by an inexperienced person. Moreover, we have learned something in the past few years from military surgeons, and now know that a penetrating wound is not necessarily a perforating one, and that those of the latter variety may spontaneously recover where the ball is of small caliber and high velocity.

Were I unfortunate enough to receive a shot wound of the abdomen I should insist on an immediate operation if the services of a competent abdominal surgeon and reasonably aseptic environments were at hand; but I am equally certain that I should take my chances on the battlefield or under conditions much the same in civil practice, where either the operator or conditions surrounding presaged disaster. Abstention from all food and drink with opium to check peristalsis early in the case will save more cases than reckless operating.

DISCUSSION.

DR. THEODORE A. MCGRAW, Detroit—There is a widespread idea that a bullet will strike the abdomen and come out after making a circuitous course. Several years ago I read a paper in which I described a number of operations on the lower animals showing this to be impossible. A gunshot wound may run around a hard substance like the scalp, but never in the bowels. In shooting through the abdomen the bullet always goes straight through. The reason the mistake is made is because surgeons do not take into account the fact that the abdomen changes its shape frequently. Sometimes the anterior muscles are away down to the backbone. The route may look circuitous, but it is not, and I feel I can say positively that a bullet never takes a circuitous course in the abdominal cavity. Contractions of the abdomen explain a great deal about the course bullets take in the intestine. If you will put a fellow through certain exercises you will see that the intestines are forced back so that the abdominal wall nearly touches the backbone. The bullet can pass to one side or the other of the small intestine and escape the coils.

The prognosis in the empty intestine is better than in the full intestine. If a man is shot through the stomach after a feast things are very different. The man who has been fasting for hours may have a wound in the stomach, but there is nothing to escape, so that the prognosis in the empty stomach is the same as in the empty intestine.

As to treatment, I wish to emphasize what every practical surgeon feels, i. e., that these patients should be operated on immediately, and in some cases it is better not to wait to make everything absolutely aseptic. If you are called to see a gunshot wound a long way from home, you had better operate immediately, using whatever instrument you may have. Do not let time go by, as extravasation will occur. Besides, we have to consider hemorrhage, of which some patients die on the table. Sometimes we err on the side of waiting to get everything in perfect condition, but the quickness of the operation is of more importance than the cleanliness. I should operate within the first half hour if I could get at the case.

DR. W. W. GRANT, Denver—This question was recently discussed at the meeting of the Military Surgeons' Association in Washington. I think the profession, the army surgeon particularly, is averse to immediate operation in abdominal wounds on the field. This question in the affirmative was advocated by an army surgeon, who has, of course, to support his view, the extreme mortality that results, as shown in the recent wars from abdominal wounds in which the intestines have been cut. This is true in South Africa and in the Philippines, according to statements recently made. Several instances are mentioned in which men were shot through the intestine and stomach and lay upon the field for twenty-four hours with absolutely nothing to eat or drink. These men recovered, while others who had taken something to drink died. This was both significant and interesting, and is in favor of the same form of treatment as that advised and brought forward by Dr. Ochsner in reference to certain forms and stages of appendicitis.

Beyond this my opinion is that the sooner the operation is done the better, and Dr. Rodman's statistics emphasize this point. A delay of only a few hours adds to the gravity and the mortality and therefore a man who has been shot, whether in the army or in civil life, should be operated on in the shortest possible time, even though we have not the most thorough aseptic conditions at our command. The sooner the abdomen is opened and the hemorrhage stopped the sooner your patient will begin to improve; the sooner he is operated on the less danger there is of fecal extravasation.

Transportation increases the gravity in such wounds in both civil and military life; consequently the soldier should be operated on by a skilful surgeon, at the "first line of medical assistance," and in civil life it is not wise to delay long in order to secure the complete equipment and advantages of a modern hospital.

DR. J. C. OLIVER, Cincinnati—The essayist has very clearly and emphatically pointed out the important fact that gunshot wounds of the chest are, when properly treated, followed by a very slight mortality. The general impression gathered from writings on this subject is that these injuries are of a very serious and often fatal nature—this impression is, according to my observation and experience, entirely erroneous. If patients do not die within the first twelve hours from shock or hemorrhage (and I think in this class of cases the terms can be used interchangeably) the vast majority will recover without serious illness, provided rest is given the injured parts. Aseptic dressing, combined with fixation of the chest, and opium to decrease the depth and frequency of respiration, are the routine measures to be adopted. My personal experience leads me to believe that with this method of treatment gunshot wounds of the chest may be classed among the more trivial injuries.

As to gunshot wounds of the abdomen—in a large proportion of these cases the patients are fatally wounded and will die, either with or without surgical intervention. One can not with accuracy say just what this proportion is, but it is undoubtedly a pretty large one. Wounds of the large vessels will prove fatal in the vast majority of cases, because of the time that must necessarily elapse between the receipt of the injury and the opportunity for surgical relief. It is surprising how long a patient may live after injury to the large blood vessels. I recollect a man in whom a bullet passed directly through the ascending vena cava. He lived long enough to be transported to the hospital and have his abdomen opened before death took place. The main causes of death in this class of cases are shock, hemorrhage and infection. The early deaths are due to the two former conditions; the later mortality is due to infection.

Fecal extravasation, at least in appreciable quantity, is not a frequent complication. Its presence is noted in about 5 per cent. of the cases, and the proportion increases with the lapse of time following the receipt of the injury. It is very rare in the cases operated on early unless the intestine is the seat of a long wound, or of an unusually destructive lesion.

Statistics very clearly indicate that gunshot wounds of an empty stomach are less serious in their results when not subjected to operative procedures. Wounds of the full stomach are rapidly fatal unless treated by early operation.

Shock is not of much diagnostic importance in cases of this class. I have seen most pronounced shock in non-penetrating wounds. On the other hand, it may be entirely absent in penetrating and perforating wounds. As an indication of penetrating, the presence or absence of shock is of but little value. The best way to make a diagnosis of penetration is by following the bullet wound with incisions.

The question of drainage following operation is an important one. The wounds of entrance and exit may be drained, as may also the tract traversed by the bullet, but experience certainly indicates that the drainage will, in a few hours at most, be limited to the immediate vicinity of the drainage tube; hence

it will not be very efficient as a prophylactic against peritoneal contamination.

The important lesson to be learned from a study of these cases is that early operations are the ones in which success is possible. Delayed operations have a very high mortality, and are useless in the vast majority of the cases.

DR. JOHN B. ROBERTS, Philadelphia—I would like to say a word as to the value of general venesection in the acute pneumonias following gunshot wounds of the lungs, as I believe it will often save life. I wish to dissent from the statement that hemorrhage and shock are the same thing. The symptoms are similar, and the surgeon may be unable to make a diagnosis from the symptoms, but shock is not hemorrhage. In the interest of scientific accuracy it is important to bear this fact in mind.

DR. A. J. OCHSNER, Chicago—In gunshot wounds of the chest the important point is immobilization, but there are few surgeons who appreciate this. Personally, I confess that the immobilization which I practiced was very incomplete until I visited the City Hospital in St. Louis and the surgeon there demonstrated to me a case of gunshot wound of the chest. The bullet had perforated the chest through and through, but the patient was perfectly at his ease and breathing quietly. The resident surgeon informed me that they had treated nineteen successive cases of these wounds by the method he should use, without any more difficulty than that which was present in the case I observed. It was three years ago that I saw this case, and since that time my experience has been the same as that described above. The manner of immobilization was much more complete than that which I had previously practiced. It consisted in the application of a plaster-of-paris cast including the entire chest, so that the breathing was accomplished by the diaphragm entirely. The cast may be constructed out of adhesive plaster by covering the chest from top to bottom with several layers of the adhesive plaster, or it may be constructed of plaster of paris. It is interesting to note the effect on the chest. Instead of continually hacking the patient begins to breathe quietly, and within a short time his anxious, distressed appearance vanishes and he is able to rest.

In gunshot wounds of the abdomen the immobilization of the intestines is, of course, of the utmost importance. Every one who has frequently performed abdominal section knows that the intestine and stomach in healthy patients are ordinarily empty, with the exception of containing gas. The experiments of Cushing have shown that if a patient receives only aseptic food for a number of days pathogenic microörganisms in the intestines are rapidly reduced to a great extent. This is one reason why in military practice the patient frequently recovers spontaneously, although the intestine has been perforated. If the abdomen in these cases were opened more frequently I think we would find perforations in many cases which now recover without operation. Healing may progress as it would in a small typhoid perforation, provided the intestines are empty. In private practice this is an entirely different matter. These intestinal wounds almost always occur in drunken brawls, when the intestines are full of food, whereas in military practice the opposite is almost always the case. Of course the difference in the velocity and the size and construction of the ball, which Dr. Rodman has so thoroughly discussed, are of vast importance.

DR. ERNEST LAPLACE, Philadelphia—When food enters the alimentary tract the stomach and the intestines distend, and the immediate result is peristalsis. In gunshot wounds of the abdomen there is an immediate extravasation. When the intestinal tract is empty the intestines are collapsed and will contract when injured, so that there is no extravasation. We need not get septic food into our intestinal tract in order to have septic peritonitis. The normal intestines contain all the germs that ever produced peritonitis, and they are held in a harmless condition by the mucous membrane. Remove the membrane and let the germs out and see what happens; this explains peritonitis. No power can tell us precisely what condition the intestines were in when the bullet struck, and we should be clever enough to make a positive diagnosis so that should we proceed immediately a clean field of operation can be prepared. We must see what we do and do it perfectly; this is the doctrine of all medical science—fulfill the indication. There are two distinct things meant when you speak of shock. There is an immediate depression of the nervous system and cerebral anemia. If there is hemorrhage, that further adds to the cerebral anemia. As far as drainage is concerned, this will depend on the extent to which the peritonitis has gone. If there is very little peritonitis we need not drain, but if the peritonitis has started, let us do what we would do to an arm that was infected.

DR. H. H. GRANT, Louisville, Ky.—Almost every point has been considered except the technic of the operation. I believe we are all in accord that operative steps are immediately indicated when the diagnosis is made. In gathering statistics given by Dr. Rodman of 260 cases collected by me the question was asked if, in any case in which the abdomen was opened for perforating wounds, it was found that the operation had done any harm, and in every one of the cases the answer was "No." I took this to justify exploration in all doubtful cases. In determining the propriety of the operation we consider what is the danger to the patient from his injury. Practically speaking, it is always either hemorrhage or sepsis that kills, and no danger comes from putting the lesion before our eyes. The closure of the perforation, the removal of escaped fecal matter and blood, and the control of hemorrhage can be accomplished in no other way. In determining whether or not all the perforations are closed, it is particularly important, if possible, to decide on the direction of the bullet, as this will help determine the extent of injury to the intestines. As soon as the cavity is opened and the hemorrhage is controlled, the first perforation should be located and marked by a strip of gauze. Search of the intestines in both directions for ten or twelve feet for other perforations will usually find all damage; the number of perforations should, as a rule, be even. It sometimes happens that the bullet passes into, without escaping from the intestines, but if not found there suspicion of its escape should lead to further exploration. Sometimes also a knuckle of intestines is knocked off without perforation, making the number of perforations odd. If one perforation be overlooked, the whole object of the operation is defeated. In private practice the intestines are usually full of fecal matter, and its escape into the cavity soon takes place. Thorough irrigation is very important, as a small amount of fecal matter will surely escape. In the only death occurring in a series of ex-cases septic peritonitis resulted from imperfect cleaning, which was very difficult, owing to the great distension of the intestines with food. The propriety of eviscerating the abdomen is sometimes justifiable; better do this than overlook hemorrhage or perforation. When the intestines are pulled out there is considerable difficulty in getting them back, but I believe it is a wise thing to do in certain cases. As to drainage, I always use it, as I believe it is safer.

DR. WM. H. WATHEN, Kentucky—We must agree with the gentlemen who advocate an immediate operation in gunshot wounds penetrating the abdominal cavity, in civil practice where the shock is not too great and where the patients so often would have infection; but in military practice, where there is a delay of from six to twenty-four hours before the patient can be operated on, and it must then be done hastily, the indications are entirely different. In civil practice, many of the cases are wounded with a full stomach, which is not usual in military practice. If you have waited from twelve to twenty-four hours, your patient may be infected beyond remedial efforts, and you will get serious results. If the patient is then infected, he may not recover, with or without operation. In civil practice we do not have the same kind of bullet wounds. The new army rifle uses a .30 bullet, which makes a very small opening in the bowel or stomach, and seldom causes immediate or secondary hemorrhage. The second wound of the stomach, filled with a liquid or semi-

liquid, as in McKinley's case, is very large and ragged. This is accounted for in part by the direct impact of the bullet, but mainly by its explosive energy imparted to every part of the liquid. This has been demonstrated by the experiments of shooting into vessels containing water. Had President McKinley been drained posteriorly he probably would have recovered, and this could easily have been done by cutting through the back and introducing a gum drainage tube and gauze into the small peritoneal cavity. When the large peritoneal cavity becomes infected, it is doubtful if drainage will help matters. It is preferable to thoroughly wipe the cavity, and close it, without saline irrigation or drainage.

DR. R. H. GIBBONS, Scranton—The first important step in the treatment of these cases is the introduction of a catheter into the bladder and the next is to introduce a catheter into the bladder before the abdomen is opened. The first time settles the question of injury to the bladder and the second time of injury to the kidney or ureter. If you get bloody urine in the first instance you can come to the conclusion that it came from the injured bladder. Although it may be that either the ureter or the kidney is injured, you should search the lines of the ureters after exposure by celiotomy to see if you can find any perforation thereof. The kidneys should be most carefully searched. I know of death, in an otherwise surgically well cared for case, due to indirect wound of a kidney uncared for.

The next important thing is to make thorough repair of all injuries. Do not be in such a hurry to get the patient off the table, as Dr. Rodman rightfully says you should, for fear of lack of full repair. If a man has died under such circumstances something may have been improperly placed or unsurgically cared for. After repair, the peritoneum should be well cleansed by flushing with hot water, run in through a funnel and tubing. This is important and, above all, we should establish drainage of an efficient character.

In perforation of the chest the fixation of the chest and shoulders by plaster of paris is very important, far more so than most any other single act in the treatment of any kind of perforation of the chest walls; and this, too, regardless of whether the wound is one caused by a missile, accidentally or otherwise, or if it should be one premeditatedly made by the surgeon. I lost a case of removal of a large costo-chondroma due to the neglect of the use of this very means of fixation, given to us by a St. Louis surgeon a number of years ago.

DR. MILES F. PORTER, Fort Wayne, Ind.—I want to combat the pernicious teaching of Dr. Wathen, when he says that he would advise operation provided shock and hemorrhage are not too great. I am not ready to say that there is no such a thing as shock without hemorrhage, but I am quite positive we seldom see it. What we call shock is really hemorrhage. Shock as it ordinarily occurs is one of the indications for early operation. If it be nervous shock, you will have done no harm by putting the patient to sleep with an anesthetic. As to the possibility of severe injury from missiles which do not even penetrate the peritoneal cavity the essayist says nothing. I would like to hear what his experience along this line has been. My own experience has led me to think that such injuries are not very rare.

DR. FLOYD W. MCRAE, Atlanta, Ga.—Five cases of penetrating wounds of the chest and abdomen have come under my observation within the last 90 days, 4 in hospital service and one in private practice; 2 were stab wounds of the chest, knife penetrating the diaphragm and stomach; 3 were gunshot wounds of the abdomen, with intestinal perforation. While stab wounds of the abdominal cavity are less fatal than gunshot wounds, the reverse has been my experience in wounds of the chest. Of my 2 cases of stab wounds of the chest, both died, one within a few hours from hemorrhage, and the other from infection of the pleural cavity from the stomach. Of the 3 penetrating gunshot wounds, one died from general peritonitis, due to an overlooked perforation, convex border of the transverse colon. The exploratory operation was done by the house surgeon of Grady Hospital. Five days later I opened the abdomen, letting out a large quantity of pus and fecal matter. Patient died 48 hours after the second operation. The second case was in the service of Dr. Cooper; operation about two hours after the injury. Several perforations of the intestine were sutured. Recovery was uneventful. The third case was a private patient, Griffin, Ga. Operation was done about 8 hours after receiving a pistol shot, 38 caliber, median line, about one inch above the pubes, which made three perforations of the ileum and tunneled the bladder without cutting through the mucous membrane of the latter. The perforations were closed in the longitudinal axis of the intestine, bullet removed from the pelvic wall. Gauze drainage. Recovery.

DR. R. HARVEY REED, Rock Springs, Wyo.—No one has made reference to the direction in which the wound is received. Those cases of gunshot wound entering antero-posteriorly are not nearly so dangerous as those entering by the side, as experiments and experience have proven. In making our prognosis it is very material to know whether the bullet enters antero-posteriorly or laterally. I have seen instances where a person has been shot four or five times, with only a single perforation, while I have seen others in which one bullet entering laterally has made eleven perforations.

As to shock and hemorrhage, there is a vast difference between the two. We have instances almost every day in which there is a great amount of shock, but no hemorrhage. Hemorrhage and shock are entirely different factors. We should, as far as possible, make the diagnosis before we open the abdominal cavity. I have seen cases that have been shot through and through get well without any operation. If you have a perforation of the intestines it is your duty to at least make an exploratory incision.

DR. B. MERRILL RICKETTS, Cincinnati—I simply speak from an experimental point of view. It is hard to listen to men telling what should be done in the abdomen, and saying nothing about the chest, although the surgery of the chest is of as much importance as the abdomen. Various experiments have shown that injuries to the lung are also treated. Hemorrhage may be checked by ligature or compression. The Italians have frequently operated for gunshot wounds of the lung. The kind of missile has been changed, and is doubtless made aseptic by the time it reaches the point of contact. It has been said that the chest should be fixed with plaster of paris; fixation for what? Is it to prevent the lung from expanding? You may fix the chest to prevent the ribs from expanding in cases of fracture, but the lung goes on expanding just the same. The lung may be removed with the ligature in a dog, and any one or more ribs may be removed. One of the principal factors is the internal mammary artery, but this can be avoided. Danger from the intercostals is not so great.

DR. S. H. WEEKS, Portland, Me.—I can subscribe to nearly all that has been said, but I wish to take exception to Dr. Grant's statement that the abdominal cavity should be irrigated. There is occasionally a case where irrigation may be necessary, but I want to make a most emphatic statement that it is bad practice as a rule to irrigate the abdominal cavity. The line of infection is along the track of the bullet, and if you practice irrigation you will diffuse the septic material among the intestines. It is better to wipe with gauze than to irrigate.

DR. C. E. THOMSON, Scranton, Pa.—I had a case of gunshot wound of the chest and the bullet was found in the chest wall by the *x*-ray. An anesthetic was given, and the man struggled desperately while taking chloroform. We could not find the bullet, and put him back to bed. A second *x*-ray was taken the next day, and the bullet was located in the thoracic cavity, lying on the diaphragm. Recovery was uninterrupted, and the patient carries the bullet to-day. In another case, where the bullet perforated the intestines in four places, the patient died five days after the shooting from an undiscovered penetrating wound of the kidney. Wounds of the bowels which were closed by Connell stitch were found at the post-mortem to be completely healed.

DR. R. H. M. DAWBARN, New York—As to controlling hemorrhage from wounds of the chest and elsewhere, where we can not directly press by some means on the bleeding vessel (medical as distinguished from surgical hemorrhage), I think our profession has almost forgotten that very old and yet best of all ways, and this applies, too, to hemoptysis. I allude to cording the extremities close to the trunk, accumulating thereby blood in them until, from partial anemia elsewhere, faintness follows; whereon there is, from weak heart action, opportunity for clotting. As a point in technic, it is best to control the circulation in only three limbs at once, shifting after, say, a quarter hour to the fourth and letting up on the first limb, and so in regular order—this for the safety of the limbs.

Regarding gunshot surgery of the abdomen, like most surgeons in civil life I have had only a modest amount of it to do. But it happens that I have prepared in my life possibly half of the junior surgeons of both our army and navy (work I no longer do); and during the late war I kept in touch with many of these former students, to learn their practical experience on a large scale. As to intestinal surgery, their testimony is that non-operative measures are safer than operative in the emergency work following a battlefield. We can readily see why. Bowel surgery demands infinite attention to detail and scrupulous asepsis; conditions not readily obtainable where a line of desperately wounded soldiers await attention. At night, too, even in the tropics, the air is chilly, and chilling of the peritoneal cavity invites fatal shock. In a word, the "morphin splint" of the wounded bowels, at once stopping suffering and checking peristalsis, saves more lives. It puts the wounded organs at rest, preventing excessive leakage of stomach contents or of feces, and giving a good chance for adhesions to seal the wounds. It is imperatively wise to give absolutely no drink and no food, in order to avoid arousing fresh peristalsis and leakage. The morphin checks thirst and hunger by compelling sleep. In every sense, it is the wounded soldier's best friend; and, in my judgment, should be supplied in tablet form to the extent of one large dose in the surgical package for emergency use which is now placed in every knapsack.

DR. W. L. RODMAN, Philadelphia—I remember Dr. McGraw's paper very well, and I agree with what he says. Such an opinion is valuable. Soft tissues will turn a bullet as well as bone. Dr. Grant's picture has brought forward the question of what is to be done in military practice, but I kept off this subject because I thought Dr. LaGarde was here. Undoubtedly we have come to a parting of the ways, so far as the treatment of gunshot wounds is concerned. Military surgeons are right from their standpoint in advocating non-interference on the battlefield in view of the difficulties under which they labor. The wounds they see are altogether different from ours. They are made by a small conical angle bullet which cuts like a knife. It does not take in foreign material, and makes an incised wound. Single or multiple perforations will not be followed by fecal extravasation, and recovery may take place. In civil life we deal with a round bullet which usually takes in foreign material and practically always makes both a contused and a lacerated wound, which is nearly always followed by fecal extravasation. The military surgeons are right to a certain extent, but we can not admit that this method will do in civil life. Dr. Oliver is correct in stating that wounds of the stomach are less dangerous than those of the intestines, and there are several cases on record to prove this. There is no question that they do tend to recovery, and if the bullet is small this makes a great difference. Moreover, they sometimes result in abscesses and discharge posteriorly, just as a perforating gastric ulcer will sometimes result in abscess. Sometimes a traumatic perforation of the stomach will repair itself without operation. I said Mr. Makin stated that a bullet would not necessarily cause a perforation of the duct, but I also said he was opposed in this view by the vast majority of military surgeons. I mentioned the names of those who were opposed to Mr. Makin's views. I believe these perforations do heal in some instances. I agree with Dr. Porter as to shock and hemorrhage. I do not believe that shock is always due to hemorrhage, but it is very generally so. Ever and never are words that have no place in surgery. Where there is profound shock we shall do well to find the case that does not have a great deal of hemorrhage, but it will not do to say that shock is always due to hemorrhage. Dr. Gibbons' point in reference to the catheter is a good one, as it enables you to eliminate wounds of the bladder and kidney. Mr. Makin says that many wounds of the bladder recovered during the South African war, and he also states that an intra-peritoneal wound of the bladder, even though it be followed by extravasation of urine, is a less dangerous injury than an extra-peritoneal. He states that the same is true in reference to the intestine, and he cites cases to support this. I do not agree with Dr. Gibbons that one can take plenty of time to these cases. Those who have had the greatest success have been those who have taken some chances rather than to eviscerate and work indefinitely over a perforation. The operation should be done as soon as possible.

SANITATION AND POLITICS.*

WALTER WYMAN, M.D.
WASHINGTON, D. C.

The subject I have chosen is one on which I have reflected for some time, but I must confess at the outset that I have not given it the deep study and research required for its thorough and exhaustive treatment, so that these few remarks must be considered simply as preliminary in character with a view to stimulating both you and myself to a deeper study of the subject and a compilation of statistics and other facts bearing on it.

In discussing this and other interesting subjects in this Section, it is well for us to recall the real object to be attained and for which this Section on Hygiene and Sanitary Science has been established as one of the principal deliberative sections of the American Medical Association.

What is the object of hygiene and sanitary science? What can it be, except the elimination of preventable disease? Now this warfare on disease, to use a military metaphor, involves two methods: one by sortie or field work; the other by fortification. By sortie we corral disease in quarantine, we isolate the diseased persons and hold in observation the contacts, we clean up and disinfect infected places and objects; moreover, we establish sanitariums and hospitals for the cure of disease. By fortification we fortify our bodies against disease, so that the assaults of the latter may be repelled. We accomplish this by hygiene, by provisioning ourselves with pure air and sunshine, potable water, the rapid and safe removal of excreta, and in the meantime by laboratory investigation learn all that we can concerning the nature and habits of the enemy.

Now of these two forms of warfare there can be no question that fortification is the more important and, dropping here the military metaphor, how much greater is the necessity, how much wiser is the prevention of disease than its cure or restraint. It is but natural that in the growth of the human family attention should have been first directed to disease itself, just as formerly in its treatment the symptoms received greater thought and attention than its etiology; but it is one of the signs

* Read at the Fifty-third Annual Meeting of the American Medical Association, June 10-13, 1902, in the Section on Hygiene and Sanitary Science, and approved for publication by the Executive Committee: Drs. Arthur R. Reynolds, George Cook and Heman Spalding.

of the advancement of civilization, of the progress made in the uplifting of the human race, that prevention is rapidly being accorded its proper relative position. Our intelligence will be blinded if we fail to recognize this metamorphosis in the science of medicine, and our intelligence will be illumined and will light up the correct paths to a higher life if we recognize and act on the principle that prevention is better than cure.

Politics has been defined as the science or practice of government, and the definitions of government are "guidance, direction, regulation, management, control; the exercise of authority in the administration of the affairs of a state, community or society." Therefore, the correct interpretation of my subject is the relation between hygiene and sanitation on the one hand and government on the other, and I am using politics in its better sense.

It is pertinent here to urge that we guard ourselves against a wrong and unpleasant definition of politics. The word is essential in our national vocabulary, but too often is used as signifying that which is objectionable and even reprehensible, but because there are bad politics and bad politicians the term should not be considered one of reproach, and the science of politics should be no more disparaged than should the Christian religion because of backsliders and hypocrites. We should divest ourselves of prejudice against the name because it may be well utilized in the advancement of hygiene and sanitation and because it actually signifies the energy, the attention to duty demanded of a people who are blessed with self-government.

It would make an interesting chapter to detail the interference caused by faulty politics with sanitary affairs. No doubt all of us at this moment have in mind instances of the shameful sacrifice of sanitary and health matters to the selfish and unrighteous interests of unworthy politicians, but the simple inveighing against unprincipled politicians and impure politics has no corrective tendency. A more effective way is by substitution, by forcing to the front worthy issues on which the best citizens and worthy politicians may unite, and it has frequently occurred to me that such issues may be found in sanitary and hygienic policies. Thus can politics be made to aid us in hygienic and sanitary reforms and in the attainment of that sanitary welfare of communities and nations which means fresh air and sunlight, pure water and house drainage, sewerage and good paving, for the enjoyment of all. These the rich already possess, but the poor do not. But the rich can not reap the full benefits of these possessions until they are shared in by the poor, for the diseases incident to the overcrowding and bad sanitation of the homes of the poor find their way into the homes of the wealthy.

How these issues may be made, even in ward politics, is illustrated by the canvass and election of a certain councilman in a southern city, who made his political fight on the disinfection of school houses. In municipal politics the issue might well be made on the elimination of slums, the condemnation of insanitary buildings, the conversion of foul alleys into streets and courts, and the erection, either by municipal authority or by corporation, of sanitary tenements for the poor, the rent of which should not exceed the rent paid for the rooms or houses from which they should be evicted.

The discussion of these measures by the people and the politicians would be a most direct and practicable method of educating the poorer and more ignorant classes of our population in the principles of hygiene and the prevention of disease.

Political issues might also be made on the appointments on boards of health, both municipal and state, and state and municipal health officers, and the sanitary ideas which they represent. In state politics, inasmuch as crime as well as disease is frequently due, as stated by Dr. Alfred Carpenter, to vicious and insanitary habits and surroundings or the neglect of sanitary laws, there may well be made an issue with regard to sanitary and hygienic requirements as prerequisite to the granting of municipal or town charters. It surely is within the power of a state to demand that its cities and towns shall be properly sewered and paved and provided with wholesome water supplies.

With regard to national politics, the action of this great American Medical Association in providing a legislative committee and for a legislative conference of representatives of each of the state medical societies, and the action already taken by this committee and this conference are significant as illustrating issues already made in the domain of national medicine and sanitation. And even in international affairs there are indications that sanitation may in the near future become an important issue in international politics. I may here refer to the Second American International Conference which met in the City of Mexico in the latter part of 1901 and adjourned in January of this year, and to the resolutions concerning an international sanitary policy adopted by the delegates to that convention. These resolutions, published in the Public Health Reports of March 21, 1902, relate both to quarantine and sanitation, and provide among other measures that the governments represented shall co-operate with each other and lend every possible aid to the municipal, provincial and local authorities within their respective limits toward securing and maintaining efficient and modern sanitary conditions in all their respective ports and territories, to the end that quarantine restrictions may be reduced to a minimum, etc. And to give effect to their findings, they further provide for annual sanitary conventions of delegates from the several republics and the establishment of an international sanitary bureau with permanent headquarters at Washington. The first conference is to be held Oct. 15, 1902, and although the program, so far as I know, has not been announced, it will probably contain reports from the several republics on their quarantine laws, their prevailing diseases and sanitary measures now in progress and those proposed; furthermore, a discussion of the principles of quarantine, the scientific investigation of communicable disease and the sanitation of seaports. Thus we see how the doctrine of sanitation is spreading, how it may become a live issue in communities, towns, cities, states and national governments, and between nations. We see how sanitation may give life to politics and how politics may be made to serve the great cause of sanitation.

How frequently do we hear of the necessity of a campaign of education in sanitary matters. This education may in part be obtained from the school and the college and the university, through the daily press and through the bulletins of instruction so frequently issued by municipal, state and national health authorities, but, in my opinion, no means of providing this special education is superior, no method of reaching those whom it is most necessary to reach—the poor and ignorant—is superior to that of making this great movement an issue of politics.

DISCUSSION.

DR. H. O. MARCY, Boston—The subject is one which is of extreme interest and importance to all of us, and it has occurred to me that it might be of some value in introducing the discussion if I gave you briefly a chapter of our own work in Boston. Boston and the surrounding towns within an area of ten miles have a population of about 1,100,000, and twenty-six separate governments. These cover what is known as Greater Boston. The work of sanitation was commenced back in the days of my revered master, H. I. Bowditch. At that time it was pretty easy to manage the sewage system of the city of Boston, which was isolated from the surrounding towns. When, however, we were called on to bring into conjunction the combined interests of the twenty-five allied towns, we found that the task was not an easy one. As a matter of fact, it cost us many years of earnest political work to get the requisite laws passed through the legislature, and some of the difficulties are not quite settled yet. There always is, and, I am afraid, there always will be, a tendency on the part of particular towns to think that they are being required to pay a little too much, or that they are not getting their proper share in value of the money expended. The system as now developed is generally regarded as a very excellent one, and I have no doubt it compares favorably with that of any city in the world, but there is no gainsaying the fact that it caused us a great deal of trouble. The first thing we recognized was that it was of vast importance that we should bring general issues under the control of a central authority, and leave local issues in charge of local bodies. When you consider the difficulties we had to encounter in dealing with Greater Boston, and think of the enormously greater difficulties that must be overcome when you come to deal with the interests of different cities and states, you will commence to realize what an extremely complicated problem it is that presents itself for solution. By way of illustration I may say a word about one of our most formidable difficulties. It related to the water supply, and a common criticism has been that if we had gone to Lake Winnipisaukee, N. H., for our supply it would have cost no more than the present system, on which we are expending $40,000,000, and we would have had an unlimited supply, which would have met our wants in all coming times, without the destruction of towns and manufacturing villages. The large obstacle was that the lake was in a different state. Had it not been for that circumstance we could have had that fine water supply and, at the same time, have furnished all the towns along the Merrimac with all the water they require, and that at a cost not greater, and possibly a little less, than we are expending on our present works. Now, I repeat, if difficulties of this kind are met in local centers of population, how much greater the difficulties must be when we come to deal with the entire continent.

DR. STEPHEN SMITH, New York City—I also was reminded while listening to the paper of Dr. Wyman of the early movements made to secure sanitary legislation, and of the innumerable difficulties the pioneers encountered. We found how essential it was, in endeavoring to secure national and state legislation and even the passage of municipal ordinances, to get the political aspects of the question rightly fixed in the minds of the leading politicians. It was the same in Great Britain. The great sanitary reforms of that country were not effected until those questions regarding the protection of the public health had been introduced into politics and thus became a strong factor in the political issues of the day that the reformers succeeded in getting adequate legislation. Lord Beaconsfield was so impressed with the popularity of sanitary reform that he formulated the rallying cry of *Sanitas sanitatum omnis sanitas* for his party. It was eagerly taken up by his followers, and carried the election, and nearly all the sanitary reforms that have been introduced in Great Britain date from that time. Nor was the influence of that movement confined to that country. It extended to the continent of Europe and to America. We had the same experience in New York. For fifteen years we sought legislation through the efforts of medical societies alone, but in vain. It was only when we entered the political field and called legislators to account publicly that we succeeded in securing the passage of the law creating the Metropolitan Board of Health, the first board of health in the United States established on sound sanitary principles. The same facts are noticeable in the history of the New York State Board of Health. For many years the effort to secure proper legislation was made entirely through medical organizations, but with no success whatever. Disgusted with continual defeats, I proposed to my colleagues to pass the bill unaided if they would retire; they assented, and I at once enlisted two leading politicians in my effort. By their aid and judicious correspondence the bill passed both houses of the legislature by large majorities at the next session. No medical man went to the capitol, and it is still a mystery in the profession as to the agencies which passed the measure. And the same experience awaits us in efforts to secure national sanitary legislation. For years the medical profession has been struggling, through its various committees and organizations, to create a central sanitary authority, but with no results. Now, happily, the whole subject has been committed to the care of judicious leaders in Congress, and we are about to realize our highest and best anticipations. In our aversion to what is called partisan politics we are too apt to forget that all measures for the protection and promotion of the public health directly affect the policy of the state and hence must receive the approval or disapproval of the dominant party in the law-making department. We should on this account be very charitable in our criticisms of health officials who seek the aid of political leaders in securing proper legislation. State medicine must henceforth be regarded as a most important branch of our profession and those who devote their lives to its service are entitled to our highest commendation.

DR. S. A. KNOPF, New York—The preceding speaker, to whom we New Yorkers are so much indebted for the sanitary improvement of our port, has given you a bird's eye view of the situation as it existed some years ago. Unfortunately, things are not going on so well now in our state. We have had a hard time to get the necessary appropriation to build a sanatorium in the Adirondacks. The matter has been in hand for two years, and they have not commenced to build yet.

There is one thing particularly important that I would like to endorse in the address of Surgeon-General Wyman. It is the statement that we must interest ourselves in politics. Not until we do so can we hope to be successful in our efforts to clean up politics or to clean up some of the awful sanitary conditions in our cities and towns. It is of the greatest importance that we should have a national health board. Whether it ought to be connected with the Marine Hospital Service or with some other department is a matter of detail which ought to be easily arranged; but not until every state, city and town board of health can look to Washington for guidance shall we be able to make real and universal progress in sanitation in our country.

DR. SENECA EGBERT, Philadelphia—I am very glad Dr. Wyman has read this paper, because the subject is of very great interest and importance. Every one of us has duties right before us. Dr. Marcy, Dr. Stephen Smith, and others have discharged theirs, but we younger men have it within our power to do a great deal, and we ought to lose no time in doing it. In Philadelphia they have done a little work in the right direction. The mayor preceding the present one takes credit to himself for having had the alleys and smaller streets laid with modern pavements, and the present mayor, supported by a general public interest, has taken up the question of a new water supply. If we could only get the votes of the people who have had typhoid fever in their families we could possibly carry any election in Philadelphia. As a matter of fact, we are now in hopes, as the result of public agitation, of having part of the city supplied with pure filtered water within a very short period, and the whole city similarly

provided for in the course of two or three years. This means the expenditure of a large sum of money, and shows what can be effected when politics are brought into play as a motive power. Another small matter I may mention. In the part of the town where I live the neighborhood was isolated by what used to be a ravine, but which has now been converted into a very pretty park. We formed an improvement association and by looking after everything that pertained to the improvement of the locality we got all the residents interested. In this way we got rid of many nuisances and, what is more important, we frequently secured the interest of the select councilman of the ward and have had his cordial help. That man appreciates the power of the association, and knows that we can largely influence the vote of the district, though the association is neither partisan nor political. Whatever improvements we get, moreover, we get not for our own locality alone, but for the whole ward. This shows what can be effected even by a small community like ours. There is a National Village Improvement Association which is doing a great deal of good throughout the country, but while much can be done by voluntary effort the coöperation of those in authority is requisite if we are to make any tangible progress, and what we most require, it seems to me, is a central head. As a rule I do not believe much in centralization in politics, but I do not see how it can be done without, in sanitation. The various cities and country districts should be divided up into sanitary districts, each with its own officers, but all acting under the guidance of a central body. Only in that way can we get good scientific results and make correlated progress. Of course there are good and bad politics, and good and bad politicians, but even if we have to deal with the appointees under a bad system, it is better than to have no system at all. The first thing to aim at is the establishment of a department of health at Washington, and afterward the dividing of the country into districts in the way I have suggested, each with its health officers, who would work in harmony for the general betterment of the public health. In Pennsylvania there is at present a prospect of doing some good work by the correlation of the efforts of different state officers. Our state forestry officials have done much good by setting apart certain reservations for the use of consumptives. Platforms in these localities are also provided, on which the patients can erect their tents and other accommodations supplied. In this way great benefit has been derived by a considerable number of afflicted persons at almost no cost to themselves. That, as I have indicated, has not come through the board of health alone, but through the coöperation and willing assistance of the Forestry Department. I simply mention it to show how other branches of the governmental machinery can be utilized for the public good.

DR. WALTER WYMAN—Some of the facts mentioned by Drs. Marcy, Smith and others appealed to me as very interesting and full of practical suggestiveness. I hope they will lead to profitable results. The discussion of these matters brings out many facts with which we are not all familiar, and which it is of the highest importance we should know.

A Subsidized Press.—As an illustration of the place occupied in newspaperdom by quacks and patent-medicine makers the following figures convey some significance. Measured by column inches, the *Cleveland Press* of December 13 contained 1,181 inches of advertisements. Of these 1,181 inches, 549, or nearly one-half, were occupied by the advertisements of quacks and nostrums. In the figures there may be a possible error of less than five inches, but the figures are very nearly correct. When a newspaper derives nearly one-half its revenue from the "fake" in medicine it is not to be expected that human nature will enable such a paper to hold unbiased views in reference to medical affairs. Until newspaper editors and publishers are all educated men, the medical profession will be compelled to contend with the opposition of those who have no conception of medical science.—*Cleveland Medical Journal.*

THE DRAINAGE CANAL OF THE VALLEY OF MEXICO.*

HENRY O. MARCY, A.M., M.D., LL.D.
BOSTON.

For many reasons our southern republic has an increased interest to the people of the United States. The marvelous development which has taken place in Mexico during the last two decades reflects, in a large degree, the progress of civilization on this western continent. Under the extraordinary wisdom, energy and foresight of President Diaz, the former chaotic governmental rule has disappeared, to be replaced by a wise and good government, making life and property interests as safe as in the United States.

A network of railways is interlacing the republic in every direction. These now measure over seven thousand miles, built in great part by foreign, chiefly American, capital. Every department of industry is being developed with an hitherto unknown energy, and the enterprising American appears as the promoter or owner in all the more prominent sections of the country. This is especially noteworthy in the agricultural and mining interests. It is estimated that $400,000,000 of American capital has been invested in Mexico during the last two years, and $100,000,000 more is estimated for the investments of 1902. Although the finances of the country are on a silver basis, they were never as prosperous as at present, and the future of Mexico holds out an inviting field to young men of established habits and possessed of a certain amount of money for investment. This national prosperity, in striking contrast with the previous history of the republic, has made possible the accomplishment of great enterprises.

One of these is the recent completion of the sewage system of the City of Mexico and the great drainage works which control the water level of the entire valley of Mexico. It was my good fortune to spend last November in the republic as the guest of the American Institute of Mining Engineers. This most distinguished body of scientists, about one hundred and sixty in number, traveled in two superbly equipped special trains and were everywhere received as the guests of the nation. A scientific meeting of five days was held in the City of Mexico, and one of the special excursions was devoted to a careful examination of the great drainage works, under the personal supervision of Don Luis Espinosa, the chief engineer. This great scientist has won an international repute for the successful completion of this stupendous engineering problem, one without a parallel among the nations. So interesting is the history of the subject that I have presumed to sketch it a little in detail.

The City of Mexico, over six thousand feet above the sea level, is located in the lower part of a great hitherto undrained basin in the mountains. This basin, irregularly saucer-shaped, is about seventy-five miles in diameter, giving between three and four thousand square miles of superficial surface of drainage area. The sides of this valley are in many places very precipitous, culminating at the highest point in the southeast by the snow-covered mountains, of which the volcano of Popocatepetl towers in imposing if not unsurpassed grandeur over ten thousand feet above the level of the valley. At the time of the Spanish conquest, these mountain sides

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Hygiene and Sanitary Science, and approved for publication by the Executive Committee: Drs. Arthur R. Reynolds, George Cook and Heman Spalding.

were covered with heavy forestry, of which the mammoth cypresses of Chapultepec are almost the only survivors. Such forest growth, of course, greatly modified the ground water and evaporation. The average annual rainfall is only about twenty inches, and under the clear sunshine of this remarkable climate evaporation is greatly in excess of most localities. Volcanic in origin, the upheaval of the strata is very diversified, and, in some parts, especially the southwestern, is overlaid by a great sheet of volcanic eruptive rock. From

Fig. 1.—Main canal, up-stream from Santa Clara bridge.

beneath this issues an abundant quantity of pure, sweet water, which is utilized at Tlalpam as the best source of water supply for the City of Mexico, although the old springs of Montezuma at Chapultepec are still in use. The old aqueduct from these springs, built by the Aztecs, has long since disappeared, and only a few arches, built by the Spanish viceroys, still remain as picturesque monuments of this early engineering work.

Fig. 2.—Mouth of canal from Lake Texcoco.

The history of the unnumbered centuries is measured, in a degree, by the accumulation of the filtrate of the waters of this basin, collected in the dead seas or lakes of Mexico. In these the soda salts are naturally in excess. The drainage of such an immense valley naturally forms at certain seasons of the year very considerable streams of water, correctly denominated rivers. The overflow from this valley was by the single stream, the Tequixquiac.

The waters of Lake Texcoco, the lake nearest to the City of Mexico, are the lowest in the valley, usually about twelve feet below the level of Lake San Cristobal, which again is about eighteen feet lower than the waters of Lake Zumpango, which forms the northernmost link of this dangerous chain. The level of the great square of the City of Mexico is only four feet and one inch above that of Lake Texcoco, and consequently is over twenty-five feet below the level of Lake Zumpango, which receives the largest influx of water of any of the lakes of the valley. This lake, suddenly swollen by excessive torrential rains, forms a junction with the waters of San Cristobal, and the combined force burst the dikes which separate them from Lake Texcoco. In this way the inundations of the city proper have occurred. All this was scientifically recognized by the Aztec civilization, and the causeways, still pointed out to the traveler, over which the Spanish charged with such dire consequences in the capture of the city, were really great dikes, built to protect the Aztec capital from inundation.

These overflows, so excessive as to endanger the population of the city, have been of rare occurrence. Yet most disastrous effects took place in 1553, 1580, 1604

Fig. 3.—St. Cristobal bridge, fourteenth mile.

and 1607, in each of which years the dikes constructed for the protection of the city were entirely destroyed, and the city itself was inundated, with an enormous destruction of property and many thousands of lives. These misfortunes compelled the government to devise some better way to avert the possible impending danger. A French engineer by the name of Henry Martin (Spanish, Enrique Martinez), was commissioned in 1607 by the Marquis of Salinas, who was then viceroy, to attempt the drainage of Lake Zumpango by the stupendous canal known under the name of the "Desagra de Huehuetoca." The plans of Martinez were very comprehensive, intended to accomplish the drainage of the lower lakes as well as that of Zumpango on the higher level, the superfluous waters of which were to be drained into the valley of Tula, on the north, by a tunnel. The latter of these plans was adopted by the government, and the great subterranean gallery of Nöchistongo was commenced Nov. 28, 1607. No nation had a larger number of men, life-long trained in subterraneous mining, than Mexico, and this experience especially fitted them for such a stupendous work. Fifteen thousand Indians were employed, work

having been commenced by a number of different shafts, and this stupendous work was completed in eleven months, which gave a tunnel of 6,600 meters in length, or nearly five and a half miles. The breadth of this tunnel was sixteen feet and height thirteen feet when finished. The northern extremity of the tunnel conducted the waters into an open cut or canal over six miles in length to the river Tula. The facing of the tunnel was composed of the ordinary sun-dried brick of Mexico, very probably the only material that Martin had at command. Very naturally this was inefficient to resist the velocity of the waters within the tunnel and soon disappeared.

A facing of wood was tried which proved to be equally inefficient. Masonry was at last resorted to, but this did not answer permanently the purpose for which it was intended, because the engineer, instead of using the elliptical arch, constructed a sort of vault, the sides of which rested on a foundation of no solidity. The consequence was that the walls were gradually undermined by the water and the vault itself in many parts fell in. The tunnel was finally abandoned sixteen years later, closed by order of the government, and the old system of dikes and embankments was again put in

Fig. 4.—Main canal, up-stream, twenty-second mile.

order. Martin was again placed in charge of the works. The rainy season having set in with unusual violence, the tunnel was closed lest the water pressure on it should be too great, when, on June 20, 1629, in a single night, almost the entire City of Mexico was laid under water. For five years ensuing the water in the streets was so deep that canoes formed the only medium of communication. The foundations of many of the principal houses were destroyed and trade was paralyzed. The lower classes were reduced to the extremest state of misery, and orders were actually given to abandon the city and build a new capital in the elevated plain between Tacuba and Tacubaya, to which the waters of the lakes, even before the conquest, had never been known to extend. In 1684, which was a year of unusual drouth, a series of earthquakes so rent the valley in various directions that the waters gradually disappeared. This was accredited as a miracle, due to the intercessions of the Virgin of Guadalupe in behalf of her miserable worshipers.

Martinez, who had been imprisoned because of the disasters to his tunnel, was again placed at the head of public works by a new viceroy, when he commenced the building of the great dike to separate Lake San Cristobal from Lake Texcoco. This is over four miles in length, thirty feet wide and ten to fifteen feet in height. It was composed entirely of stone, with buttresses of solid masonry on both sides and three sluices, by which, in any emergency, a communication between the lakes could be effected and at the same time regulated. The entire work was completed in eleven months, although at the sacrifice of many lives, since the welfare of the Indians was held in little esteem.

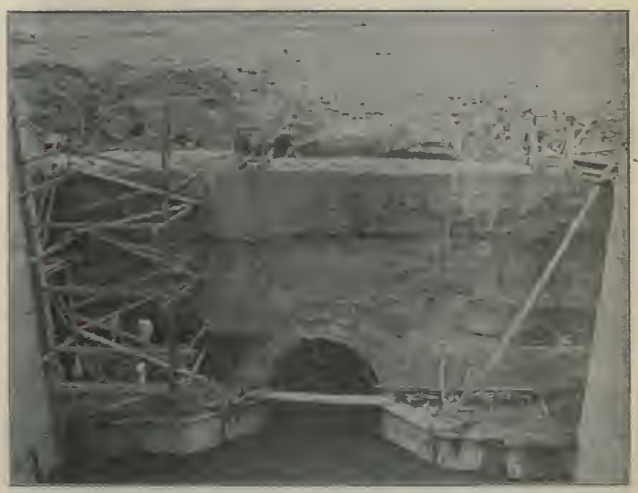

Fig. 5.—Entrance to tunnel.

The tunnel of Martin proved to be of great service, until finally it became choked by accumulated debris, and one hundred and thirty years after its completion it was determined to change the tunnel into an open cut or canal, and the work was concluded in 1789. The highest elevation necessary in cutting this canal varied from one hundred and fifty to two hundred feet, with a linear measurement of over thirty-six hundred feet.

Fig. 6.—Front elevation of dam.

To obtain such an immense depth of cutting the width was necessarily from two hundred and fifty to three hundred feet. The entire length of the cut was 67,537 feet, or seven and one-half miles, and yet all this immense mass of material was removed by hand labor and carried on the backs of the docile Indian and deposited on either bank. It is said that the lives of more than twenty thousand laborers were sacrificed in this stupendous work.

It was shown that by far the greater part of this expenditure would have been saved had this great engineer, Henry Martin, been permitted to carry out his first plans as he designed them, since the size and construction of his tunnel were greatly modified to save expense.

Martin also designed to build the tunnel at a lower level, in order that he might the better control the waters of the southern lower lakes.

This was about the state of affairs until the revolutions in 1810 and 1820, during which period all public works were abandoned, and the great canal became choked by debris, thereby greatly lessening its efficiency. The heavy rains of 1865 again inundated the city and valley of Mexico, resulting in enormous damage. However, the political events prevented entering on any measures worthy of record.

The present elaborate scheme for the proper sewage of the city and the drainage of the valley of Mexico was inaugurated by President Diaz in 1879, and the work was first under the charge of the engineer Don Luis Espinosa, who commenced to serve on the drainage works in 1871. He based his deductions on the average volume of water within the valley during a period of fifteen years, which gave him a comparatively safe basis for the estimated dimensions of the tunnel, which resulted in a calculated flow of seventeen and a half cubic meters per second. The work was completed March 17, 1900, at a cost of about sixteen million dollars, which included the entire outlay of the board in charge from 1886.

Fig. 7.—Rear elevation of dam.

Fig. 8.—Outlet of tunnel.

These works are now in full completion, and five objects are attained. First, the prevention of the inundation of the valley; second, the reception of the sewage from the City of Mexico and its discharge outside of the valley; third, the control of the water level of the valley; fourth, the use of the outflow fall for dynamic purposes; fifth, by irrigation for agricultural uses.

The works are composed of three principal parts, a canal, a tunnel and discharge cutting. The canal starts on the eastern side of the city and continues on that side to the Guadalupean range, between it and Lake Texcoco. A little before reaching the sixteenth mile it changes its direction toward the northwest, diagonally crossing Lake San Cristobal, part of Lake Xaltocan and through Lake Zumpango, passing close to the town of Zumpango before reaching the tunnel. The canal has a total length of nearly thirty miles. The bottom has a level of about eight feet at its beginning and at its end of about twenty feet, which level has its fixed measurement at ten meters below the line marked on the west tower of the cathedral, on the spot that was formerly occupied by the lower tangent of the Aztec calendar before it was removed to the museum. The canal has a uniform grade of about two feet per thousand. The depth of the canal below the surface at the starting point is about sixteen feet, and at the commencement of the tunnel about sixty-five feet. The sides have a slope of forty-five degrees and the width at the bottom is sixteen feet for the first sixteen miles and about twenty feet for the rest of the canal. These first sixteen miles may be considered as a prolongation of the great sewer, since it chiefly receives the sewage. The rest of the canal has communication with Lake Texcoco, and is intended to govern its waters, as it is the lowest in the whole valley and can receive the waters from all parts, for which reason the canal is designed to carry the largest volume that could pass through the tunnel, seventeen and a half cubic meters per second.

The ground through which the canal has been opened is essentially a clay formation. The filtrations or ground waters were found to be sufficient to cause a flow of two and a half cubic meters per second. The canal is crossed by four aqueducts and thirteen bridges, four of which are steel for railway service. The canal ends in a dam, the walls of which are built of stone and the front of which is strengthened by pilasters. The upper part, where the mechanism is placed for moving the sluice gates, has a width of twenty-five feet. These gates are moved on rollers in frames set into masonry. These raised, the water rushes out in a cascade on account of the difference of level between the bottom of the canal and that of the tunnel, amounting to about eight feet. The object of the dam is to control the discharge of the waters from the canal and stop the current whenever found necessary.

The entrance of the canal which receives the waters consists of an arch with the radius of five meters, supported on vertical walls. This section gradually diminishes until it is reduced to that of the tunnel, so that between the commencement and the final point of reduction it is the section of a cone.

The tunnel is a little over six miles long, the height is about fourteen feet and the width about thirteen. The tunnel has a brick lining of about sixteen inches.

At a distance of four hundred meters from each other are twenty-four shafts, having a width of two by three meters, the deepest of which is about three hundred feet. One of these I examined, being let down to the bottom by a modern elevator.

The tunnel opens into a discharge cutting, which is the third and last of the principal parts that compose the work and was the first to be completed. It is about a mile and a half in length and was formed by opening a natural excavation made by the waters in the ravine Acaplan, the stream having been turned by a special canal. All the water flowing through the canal and tunnel is utilized for motive power and afterward discharged into irrigating ditches and used for purposes of fertilization.

This stupendous piece of engineering is entitled to take the first rank in the solution of modern sanitary problems, and compares favorably with our own sewage system of Boston and the modern drainage works of the city of Chicago. The conditions of the problem of Boston render it impossible to utilize the outflowing currents for dynamic purposes. In this respect, however, Chicago has a better fortune, since the outflowing currents from the lake are being utilized for motive power; but Mexico, most of all countries needing irrigation, utilizes the drainage of the entire valley, enriched by the albumin excreta of her large population, for plant life, rendered doubly effective by climatic conditions which permit successive crops for food production during each of the months of the entire year.

FIG. 9.—Cut at outlet of tunnel.

Of the admirable sewage system of the city proper, I need make but brief mention, since it is not unlike the modern systems of sewage adopted by the chief cities of the world. The large main sewers discharge into the grand canal and are built of brick. The smaller sewers are made of vitrified clay pipe. No pumping is required except for the purpose of flushing the sewers, which is done by forcing the water from the springs found at a higher elevation at the south of the city, and is carried to the sewers by means of cast-iron pipes. In this way it is rendered possible to flush the whole system of sewers in the city every day by sudden rushes of water, which flow through the pipes with a velocity of one meter per second, although in many parts this can be more than doubled. It is undoubtedly not necessary to flush the entire system every day, but if for any reason this may seem desirable it is only necessary to employ four men for this purpose in each district, and as there are only five districts, twenty men only will be required to clean the whole of the sewers every day. These existing conditions are so favorable that they are almost unique, and the board of public works calls especial attention to the fact "that up to the present date there is no city in the world that can flush its sewers every day as can be done in Mexico, whenever it is considered necessary or desirable to do so."

The details of the dimensions of the sewers have been carefully studied from data covering several years. The large collecting sewers, built of pressed brick with cement mortar, are circular in form with a diameter of about eight feet, and these are carefully ventilated with every precaution taken to prevent silting.

The cost of the work now completed under the direction of the sanitation board amounts to about six million dollars, but this sum total of expense, and also of that of the drainage canal and tunnel, of which it is a part, must be considered comparatively small, since the labor cost is scarcely more than a third as much as in the United States.

FIG. 10.—Cut at Tequixquiac. Terminal canal. End of the work.

We have as a result the capital city of the republic rendered safe from future inundations, the ground water of the valley kept at a desirable level, the sanitary condition of the City of Mexico comparable to that of any other on the continent. The City of Mexico already possesses a population of 400,000 people, and is growing with a rapidity of one of our western cities. It is lighted by electricity, equipped with lines of electric cars, and its main avenues are paved with asphalt. The genius of the twentieth century broods over the entire republic, and the patient, downtrodden people are awakened to a new life in their endeavor to keep step with modern civilization.

MEXICO, May 28, 1902.

Dr. Henry O. Marcy, 180 Commonwealth Ave., Boston.

Dear Sir:—I am pleased to reply to your welcome letter of the 21st of last April, and ask you to excuse my delay.

You wish to know the area of the Valley of Mexico which is drained. If what you wish to know is the total area limited by the crests of the ridge of mountains encircling the valley, I may say it is estimated to be actually 8,060 square kilometers (3,125 square miles). But if you wish to know only the area of the lakes (marshes) which exist in the bottom of the valley, it has been a variable one.

Normally it is estimated at 511 square kilometers, distributed as follows:

Texcoco	272.2
Zumpango	21.7
Xaltocan	54.1
San Cristobal	11.0
Chalco	105.0
Xochimilco	47.0
	511.0

In times of flood the area of the lakes is increased. The last of these inundations took place in 1866, and it is estimated that the area occupied by the lakes was 844 square kilometers, of which that of Lake Texcoco was 438; 213 to those of the North, Zumpango, Xaltocan and San Cristobal, 193 to those of the South, Xochimilco and Chalco.

The mean rainfall in the Valley of Mexico is represented by rise in the rain meter of 0.52 m. (about 20 in.), according to observations of the five years preceding 1901-1902. It should be observed that there is less rain in the northern region than in the southern. On a separate sheet is a statement of the rainfall observed, giving an average of 0.52. In the City of Mexico the average rainfall is considered to be 0.62 m. (24 + in.).

The evaporation has been little studied. Observations made in special metallic vessels show that evaporation takes up from 5 to 8½ millimeters each 24 hours in the dry months from October to April, making an average of 6.8 millimeters. Other observations show 3 millimeters on the surface of the canals and lakes.

Another of your questions is: How low can the level of the lakes be reduced without affecting unduly (unlawfully) the level of subsoil water, unfavorable to vegetation in the valley? The extreme lowering of the level of the lakes does not affect the level of the subterranean (subsoil) water. This level has altered only in the zone through which the canal and drainage tunnel pass, lowering it from 5 to 8 meters; but this zone has been arid naturally, and therefore there has been no appreciable injury to its vegetation.

Finally, you desire to know by what per cent. it is hoped to reduce the quantity of salts of potash and soda, which are the injurious elements in the soil, as a result of the regular drainage of the valley.

The salts of soda are the only ones to be taken into account since the salts of potash are properly only present as traces. These salts of soda are found in the waters of Lake Texcoco in the proportion of 5½ or 6 thousandths; as soon as these begin to be eliminated there will remain those from the filtration of the subsoil which feeds the drainage canal, in which the salts of soda are reduced to 4 or 5 ten thousandths, and this is the minimum to which one can hope to reduce the brackishness of the water which will come from the valley in order to use them in irrigation.

I hope that these are the facts for which you asked me, and that I have been able to answer them to your wish.

I take this opportunity to repeat to you my sincerest regards, etc. [Signed] LUIS ESPINOSA.

DISCUSSION.

DR. BENJAMIN LEE, Philadelphia—Those who accompanied the Public Health Association to Mexico some years ago will remember a delightful day we spent in examining this tunnel, then in process of construction. Dr. Marcy has not used extravagant language in his estimate of the magnificent conception of the undertaking and the admirable manner in which it has been carried out. These works are simply stupendous. That is the only word that can properly be used to describe them. They have been carried out by a combination of mining and hydraulic engineering and native labor which in some repects was amusing. A great deal of the actual labor was performed by natives who filled baskets with the stone, earth and debris required for making the embankments, and placing the baskets on their heads carried them up the steep banks. Shortly before our visit the engineer in charge of the operations had decided that he would relieve the toiling Indians of this awful burden. Accordingly he imported a large number of American wheelbarrows. The natives were delighted when the barrows arrived. They thought them most useful contrivances, and divided them up with great care and interest. Next day the engineer went up to see how the work was going on, and you can imagine his surprise to find all the natives carrying the wheelbarrows on the tops of their heads.

Americans visiting Mexico for the first time generally go with the idea that they are going to teach the people a great deal. When they get there they frequently find themselves pretty well taken down. Dr. Marcy has mentioned the fact that you can travel with as much safety in Mexico as in the United States. I wish to surpass the Doctor's statement. I say you travel with much greater safety. There are no trains held up there. At every station going through these immense deserts you find a squad of mounted police. They patrol every mile of the railroad, and the result is that, while here scarcely a month passes without acts of brigandage and murder being committed, in Mexico that sort of thing is now obsolete.

There is one other point that struck me particularly when I was in Mexico. Most of us who are connected with boards of health find ourselves hampered by want of means. The State Board of Pennsylvania has a miserable little office on the ninth floor of an office building. Some state boards are better off, others worse. In Mexico the Superior Board of Health has a magnificent palace with a suite of rooms, ten, twelve or perhaps more rooms—each devoted to some special branch of work with all the arrangements admirably systematized. All the officials, moreover, are well paid. The chief engineer of the board is a man of great intelligence and ample salary, and the entire work of the board is carried on in such a way as to be an object lesson to visitors from this and other countries.

A third matter: The American Academy of Medicine, which has just been in session here, has been endeavoring for years back to raise the standard of education in the profession in this country. They are endeavoring to reach the point when every physician must be a college graduate. That condition has existed in Mexico for thirty or forty years. No man can commence his medical studies without having previously taken his degree in arts, and the result is a high standard of education. I assure you that if you have an opportunity of visiting Mexico you will come back wiser and better men.

SPORADIC CRETINISM IN CHILDREN,

WITH REPORT OF A CASE FROM THE UNITED HEBREW CHARITIES DISPENSARY.*

ROSA ENGELMANN, A.B., M.D.

Assistant Clinical Professor of Pediatrics, Rush Medical College.

CHICAGO.

TERMINOLOGY.

To J. Hilton Fagge, in 1871, belongs the credit of distinguishing sporadic from endemic cretinism and assigning to it the name sporadic cretinism. Jacobi was the first in America to present a sporadic case to his colleagues. Townsend and Lloyd, respectively, published "A Case of Congenital Cretinism" and "Sporadic Cretinism" before Osler's comprehensive monograph on this subject appeared in 1893. In 1897 Osler had collected 60 cases in America. Bullard, Booker, Rotch, Fruitnight, Northrup, Peterson and, most conspicuously, Koplik have augmented the literature with a special reference to the incidence of this disease in infancy and childhood. Heubner recently raised the point as to a more suitable name for this disease when occurring in early life. He protests against the term myxedematous idiocy, since neither relative nor absolute idiocy need accompany the infantile form of this disorder. I agree with him on this score, and on the further ground that pronounced myxedema may likewise be wanting, and that idiocy and cretinism are

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Diseases of Children, and approved for publication by the Executive Committee: Drs. Edwin Rosenthal, H. M. McClanahan and Samuel W. Kelley.

terminal and preventable states, dependent on absence of or disease of the thyroid gland. Hence close reasoning and expression requires that this disease in childhood be called "sporadic, infantile, congenital and acquired athyrea," or "sporadic, infantile, congenital and acquired myxedema," and that the terms "sporadic cretinism" and "myxedematous idiocy" be confined to the untreated and adult cases.

HISTORY OF RESEARCH.

As late as 1896 Eichhorst said: "Myxedema is very infrequent in childhood." Since that time observation has proven the fallacy of this observation. Again, Ewald's dictum as to the absence and infrequency of congenital myxedema in children has not been sustained, and he himself has lately exhibited such patients. Both congenital and acquired cases of infantile myxedema have been studied and discussed in Germany by Heubner, Escherisch, Simon, Siegert, Stoelzner, Quincke, Neuman and others. Hertoghe of Holland has brought the subject up to date. Great Britain, by such writers as Bramwell, Beach, Pruden, Ord, Horsley, Murray, Mackenzie and Thompson, has widened this nosologic horizon. Such a body of workers and illustrative cases surely demonstrate the importance and frequency of this generally unrecognized disease.

In our country Koplik is the one who has been earnestly studying and pleading for its earlier recognition and differentiation from other diseases, such as rachitis, rachitic dwarfism, different forms of idiocy, infantilism, lipomatosis universalis, hydremic anemia. He has made the diagnosis before the third month of life, and hence has obtained the most satisfactory results from treatment. He reports one or more cases in the past year. Packard another. I have seen 3, Neuman of Berlin 5, Ewald 3, Heubner 1 in private and with Stoelzner 4 additional cases in polyclinic practice; 18 recorded and probably numbers of unrecorded cases in one year; certainly not an infrequent disease of infancy and very significant of growing knowledge and diagnostic acumen. In a collection of 52 cases in Great Britain half of the patients presented symptoms before the eighteenth month, and among the 52 cases enumerated by Fletcher Beach 9 were congenital. In Osler's 60 collected cases 18 were children, and 2 of these were of the congenital type.

ETIOLOGY.

Heredity seems to be a factor in the adult form. Its influence has not been determined in the infantile variety. Scanty statistics with reference to sex, nationality, climate and country on this subject prevent conclusions as to their etiologic import.

There is a growing belief as to the infectious origin of this disorder, but proof is still lacking. Myxedema is an infrequent but acknowledged sequel of such infectious diseases as typhoid, rheumatism, syphilis and erysipelas. What it is, however, that causes absence of anomalies and disturbed function of the thyroid gland and the consequences of the same, is not determined. Experimental work is being done and the importance of the parathyroids in the human dwelt on. The latter are known to develop in advance of the thyroid lobes and to be concerned in the nutrition of the general nervous system and in the regulation of the cerebral circulation.

The animal experiments of Vesale, Generali and Edmunds show that ablation of the parathyroids, with preservation of the thyroids, results in the disappearance of the thyroidal colloid substance and substitution by a watery secretion, making round vesicles, into which branching cells grow, similar to the histologic-pathologic picture of a compensatory hypertrophy of the thyroid gland. These findings apparently imply the assumption of a secretory function by the parathyroids, and a storage function by the thyroids. The interdependence of nervous control and secretion is recognized, but as to whether the one or the other is the primary causal factor is undecided. Exner and Edmunds, by removal of the superior and inferior laryngeal nerves of one lobe and a thyroidectomy of the opposite lobe, produced tetany in the dog experimented on; evidence of the regulation of thyroid secretion by the central nervous system. Microscopic sections of the above thyroids after this neurotomy showed, first, complete absence of colloid material, and second, incursion of the cells into the cavity of the vesicles, viz., a typical picture of compensatory hypertrophy, above referred to. Thus anomalous innervation seems to be the probable cause of defective secretion and the mainspring of the vicious circle. Von Cyon states that in goitrous animals and in athyrea of humans the excitability of the vagi (the vasodilators and inhibitors) is diminished or abolished while that of the sympathetic (the vasoconstrictors and accelerators) is increased.

DIFFERENTIAL CHARACTERISTICS.

The landmarks or differential characteristics of this disease in infancy and childhood are first and foremost:

1. Absence of atrophy or disease of the thyroid gland.
2. Mental torpidity and physical backwardness.
3. Weak musculature.
4. Paleness, puffiness and dryness of the skin with later a thickening and inelasticity of underlying tissue.
5. Abdominal distension.
6. Constant existence of umbilical hernia, that disappears promptly on thyroid feeding. Parker and Sargent call attention to this defect that in histories, at least, is overlooked, but always illustrated in the pictures of cretins, they say.
7. Obstinate constipation.
8. Not a retarded but a rudimentary dentition, evolutionarily parallel to that of a normal child of the same length or height as the cretin.
9. A brachycephalic skull and a general skeletal arrest more marked in the long bones; a dwarfism, due to slow enchondral and osteal diaphyseal progression, but not to an epiphyseal cartilaginous hyperplastic growth and an excessive deposition of the bone cells as seen in rickets. The process is a slow, lineal, symmetric delay of ossification rather than an epiphyseal and periosteal overgrowth.
10. A radiographic verification of this fact, demonstrating the parallelism and symmetric development of the long bones of the cretin as compared to that of a normal child of corresponding height, but not of corresponding age.
11. A radiographic exhibition of the absence of partial or backward evolution of the small bones of the hands contributing with the associated shortening of the phalangeal and metacarpal bones to the spade-like appearance of the hands.
12. The presence of Koplik's stigma of degeneration, viz., an excessive prominence of and over the os pisiformis separating the wrist crease from the antithenar prominence. Koplik does not believe that this deformity is consequent on pressure from crawling, since he has seen it in a three-months-old babe.
13. Diminution of the white and red blood corpuscles and the hemoglobin percentage. A progressive anemia.

14. Small heart, slow and almost impalpable pulse, cold and mottled surface, subnormal temperature.

15. Suprascapular and supraclavicular and other connective tissue or colloid pads. See Figs. 1, 2 and 3.

16. Hoarse, low-pitched cry and voice.

17. Peculiarities of posture and gait manifested when standing by a broadened base and by a swaying of the body when the feet are brought together, with closed eyes and by a sluggish gait.

CORRELATION OF THYROID, THYMUS AND PITUITARY GLAND FUNCTIONS.

Kocher was the first to indicate the direct influence of the thyroid gland on bone and blood formation. Virchow, in 1853, announced that dwarfism of rickets

Fig. 1.—B. L., cretin, at the age of 3. No treatment.

took place after the disease process had ceased and was a result of premature ossification. Bourneville, in 1890, Telford Smith and Horsley, in 1896, and later Hellier and Hertoghe experimentally and histologically proved that the skeletal changes of cretinism were absolutely opposed to those of rachitism.

Klebs had already noted the lack of distinct zones of ossification in the long bones of cretins. Feldman, Hofmeister and Eichelberg, in a very recent experimental and histologic work, demonstrate a distinct cartilage atrophy or dystrophy, as a result of thyroidectomy in dogs. These microscopic specimens showed a distension and separation of the epiphyseal cartilage with dissolution of its ground substance and formation of vesicles with shrinkage and destruction of the cellular elements. Mikulicz and Quincke are of the opinion that the offices of the thyroid and thymus glands are intimately correlated. The diminution of the leucocyte count in athyrea, and a preponderating number of persistent

Fig. 2.—B. L., at the age of 3½, after six months' treatment. He clings to the railing for support.

Fig. 3.—B. L., at the age of 7 years 1½ months; after two weeks' thyroid feeding.

thymus glands at the autopsies of cretins would seem to indicate such a correlation. Ord and Mackenzie describe enlarged thymus glands at the postmortems of all cases of Graves' disease observed by them. Hektoen, in his exhaustive work on this subject, concludes that the coexistence is more than accidental.

Some unknown connection between the pituitary body and thyroid gland is assented to by Poufik and others, and the hypophysis cerebri is supposed to act compensatorily in diseases of and absence of the thyroid gland. Packard's postmortem of a child cretin revealed an enlarged pituitary gland, calcareous degeneration of thyroidal and cerebral vessels, a cerebral abscess, fatty liver, granular spleen and swelling of cardiac muscle.

A section in Quincke's case of acquired myxedema, in which at the sixteenth month the thyroid was pea-sized and had vanished at the fourth year, revealed atrophy of the thyroid, diminution in size of the pituitary and smallness of the thymus glands. In another postmortem on a 3-year-old child, which had suffered from acquired myxedema, the thyroid was replaced by fibrous

Fig. 4.—B. L., at age of 9 years and 4 months, after two years' treatment. (Photograph taken July, 1902.)

tissue; the hypophysis was much congested and showed areas of increased cystic formation.

Poufik's observations and the histories of a few cases suggest the common heredity of acromegaly and myxedema. A father is cited to have been suffering with acromegaly and a daughter subsequently with acquired myxedema. Another instance is that of a father becoming acromegalic fourteen years after the birth of a cretinous daughter, whose dulness and dwarfishness were not noticed until her fifth year.

Sternberg gives the following points of similarity between the two disorders: The tongue of cretins is often large, the lips puffy and thick, the nose snubbed and short. Long bones in cretins are thick and short. The jaws of both acromegalics and cretins are prognathous. An enlarged sella turcica is found in skull of both and frequently a hypertrophied hypophysis. Indolence in both is marked and the skin of the back of the hands of acromegaly is much like that of myxedema. In acromegaly the thyroid gland is abnormal when examined histologically. An overgrowth of the hypophysis has been discovered to compensate for loss of thyroid function.

Relevant to this question of associated and correlated function are the physical and clinical findings in dwarfism, gigantism, asymmetric myxedema, acromegaly, micromegaly, scleroderma, etc.

Opinion is unanimous as to the benefit of thyroid feeding and as to an improvement proportional and constant according to its early institution and continuance. A perfect mental and physical restoration is thus dependent on a timely diagnosis and the establishment and continuation of this medication. Koplik and others assure us that the most rapid and brilliant effect takes place within the first six weeks of treatment. This apparent mental and physical growth spurt is a probable "making up for lost time," that settles down to a gradual evolution similar to that of the normal individual, so soon as the cretin's skeleton conforms to or catches up to that of a normal child of corresponding height. Ewald, Thompson and others believe, however, that continuous treatment causes a uniform growth and intellectual progression. The following table of two of Ewald's cases illustrates this belief.

GIRL 8½ YEARS OLD, DISEASE NOTICED AT FOURTH MONTH.

June 29, 1890, 31⅞ inches in height.
March 19, 1891, 32⅛ inches in height.
Jan. 8, 1893, 34½ inches in height; began thyroid feeding.
Feb. 13, 1893, 35½ inches in height; grown 1 inch in 1 mo.
June 30, 1893, 36¾ inches.
Feb. 8, 1894, 38½ inches in height.
May 11, 1895, 42½ inches in height.
March 8, 1898, 46 inches in height; normal of 8½-year-old.

7½-YEAR-OLD GIRL; DISEASE SINCE BIRTH.

Aug. 16, 1894, 30 inches in height.
Oct. 4, 1894, 31¼ inches in height.
Nov. 7, 1894, 32 inches in height.
Dec. 17, 1894, 33½ inches in height.
May 9, 1895, 36½ inches in height.
May 21, 1898, 46¼ inches in height.

Showing gradual continuous growth through four years of treatment.

THE AUTHOR'S CASE.

Thompson's patient was not thyroid fed until her third year. At her fifth year she outclassed her normal schoolmates of the same age. My patient did not regularly receive thyroid feeding until his seventh year, and his growth progression compares favorably with Ewald's cases. While mental and physical betterment is marked it is not commensurate to his skeletal improvement. As a matter of experiment he was placed on pituitary gland extract, and thyroid extract was omitted, when a general mental and physical retrogression was noted with, however, a decided accession of long bone growth. On the restoration of a regular morning dosage of thyroid gland extract and the continuance of an evening dosage of pituitary gland extract the child returned to his normal state, and still continues to improve, although he does not yet approximate to the normal of an 8-year-old, but rather about that of the normal for a 3-year-old. (Since this was written he has grown an additional inch and one-quarter in three months.) The history of my patient is as follows:

Benjamin L., 7 years 1 month old, weight 39⅜ lbs., height 2 feet 11 inches. About normal for 3-year-old child. Was a

nursling. Born at full term in America, of Russian parents, not related. One of eight children, one of whom is paraplegic. No family history obtainable. The mother has a medium-sized parenchymatous goiter, unaccompanied by symptoms. Has been, and is, a healthy woman. She noticed that this child was unusually cold and pallid at his ninth month, and that he did not act as a child of his age should. He was obstinately constipated from birth and had a pot belly without umbilical hernia or signs of rickets. Did not sit up until after his first year and did not walk until the middle of his third year. No eruption of teeth until after the first year, and the anterior fontanelle was not closed until his fourth year. Survived croup at his sixth week, and passed through attacks of measles, scarlet fever, diphtheria and pertussis. Began to talk imperfectly in a low-pitched, hoarse voice during his fourth year, and until he was placed under treatment; suffered also from incontinence of urine and feces. At 3½ years, after which for a short time he was placed on thyroid feeding, he presented the typical signs of a myxedematous idiot. See Figs. 1 and 2.

When first seen by me at his 8th year he was dwarfed to the size of a 3-year-old child; walked with waddling gait and stood with a broadened base, clinging to something for support. He swayed when he closed his eyes. His head was too large for his body. He presented a stolid, unintelligent, bloated, ashy countenance, with wrinkled forehead, flattened, broad, thick nose and thick lips, behind which were the decayed, deciduous teeth. His hair was slightly roughened, but plentiful. When asked his name he huskily and unintelligibly muttered it. There was mental apathy and slowness of speech. His neck was short and thick. His skin was so harsh and dry that, on removal of his clothes, the scales showered about him. He was cold to the touch and the skin was mottled. There was also thick, boggy, subepidermic infiltration more pronounced on the extensor surfaces of the extremities; and supraclavicular and suprascapular colloid pads. They also existed on the dorsal surfaces of the feet and hands. The temperature was 98, pulse 76, hardly palpable over the radial artery; the respiration 22 per minute. Heart small and apex beat hardly palpable or perceptible. Lungs normal. Thyroid impalpable, absent. Spleen and liver normal; pendulous abdomen; small, shortened and thickened extremities. Upper and lower extremities without other deformity except fatty tumors of the dorsum of the feet and hands. After two weeks' thyroid feeding he began to look and act more intelligently. No albuminuria, no glycosuria. See Figure 3.

That anemia is a pronounced characteristic of cretins is proved by his blood examination made May 3, 1902: Hemoglobin, 65; corrected, 71; no poikilocytosis; reds, 3,993,600; no leucocytosis. Differential count: small lymphocytes, 23 per cent.; large lymphocytes, 28 per cent.; indented lymphocytes, 2 per cent.; polymorphonuclear neutrophiles, 44 per cent.; polymorphonuclear eosinophiles, 3 per cent.

Synopsis of History and Treatment.—First seen March 27, 1900; 3 feet in shoes, 2 feet 11 inches in bare feet. Aged 7 years 1 month. Weight, 39⅜ lbs.

March 30, treatment began.

May 11, 2 feet 11¼ inches. (Grown ¼ inch.) Weight, 35 lbs. 10 oz. Lost 4⅜ lbs. Abdomen less prominent; fatty tumors disappearing; talks plainer, countenance brighter. Given 3 grains thyroid extract, t.i.d.

May 15, 2 feet 11¼ inches. Weight, 34¾ lbs. Temperature, 99. Shows a little color in ear tips and cheeks (before this ashen white).

May 24, 2 feet 11½ inches. Weight, 35 lbs. Has grown ½ inch. Temperature, 99.2. Disappearance of incontinence of urine and feces. Given 4 grains, four times a day.

June 14, 2 feet 11¾ inches. Weight, 34½ lbs. Has lost ¼ lb., gained ¾ inch in height. Temperature 100.8. Walks better, talks plainly, color in cheeks and lips; temperature above normal; urine normal.

July 24, 3 feet ½ inch. Weight, 29½ lbs. Has lost 5 lbs., and for the first time in his life perspired during hot weather.

July 27, weight 32 15/16 lbs. Can stand with a firm base, without grasping something for support. No longer sways on closing eyes; can bring feet together; runs easily; skin moist; temperature, 99.8; urine, no sugar nor albumin; pulse perceptible. Reduced thyroid extract to 2 grains, a. m. and p. m.; no symptoms of thyroidism except slight rise in temperature.

October 2, 3 feet ½ inch. Weight, 36¼ lbs. Had intermittent feeding during summer and passed out of observation until October 2, when he had gained in weight, but had not grown any. Skin again rough and scaly; abdomen enlarged, reappearance of supraclavicular pads; (eruption of one permanent molar and cuspid). Thyroid extract, 3 grains t.i.d.

October 26, 3 feet ⅝ inch. Weight, 38¼ lbs. Gained ⅛ inch in height; total gain, ⅜ in.

November 30, 3 feet ⅝ inch. Weight, 38 lbs. Temperature, 100; pulse, 88; thyroid, 2 grains, t.i.d. until January 24.

Jan. 24, 1902, 3 feet 1½ inches. Weight 37¾ lbs. Grown ⅞ inch in this interval, or total of 1½ inch. Hemoglobin 66.57. More intelligent, talks quite fluently in low voice, color in cheeks, lips and ears. Skin not so dry or harsh; urine normal.

February 26, 3 feet 1½ inch. Weight, 37¾ lbs. Stopped thyroid gland extract.

March 5, 3 feet 1¾ inches. Gave pituitary gland extract, 1 grain morning and evening, as an experiment on growth.

April 19, 3 feet 2 inches—¼ inch gain. Weight, 38¼ lbs.—½ lb. increase. Intercurrent bronchitis. Suprascapular pads reappeared, skin dry and harsh, he looks loggy; abdomen prominent, constipated; grew ¼ to ½ inch in a little less than seven weeks, but mother said child retrograded decidedly in every respect. Gave thyroid, 2 grains, morning, and pituitary gland extract, 2 grains, evening. Temperature 100.

May 15. Again became thinner, skin moist. Temperature, 99.2. Fatty tumors disappeared, abdomen smaller, limbs more symmetrical. Appeared bright. Permanent incisors cut. Greater growth symmetry and intelligence. He is still dwarfed, as I believe he always will be, since regular treatment was instituted too late for a perfect restoration. (Since writing the above the boy has grown 1¼ inches and has become more intelligent.)

DISCUSSION.

DR. E. SHELLY, Atchison, Kan.—I have had a case of this sort under observation for the past seven years. When first seen by me the child was 5 years old, but had the appearance of a child of 6 or 8 months. The child has improved, but now, although 12 years old, has a mental development of a child of 6 or 7 years. She takes the thyroid extract every

morning, and is apparently in good health. At first, the thyroid was pushed until the onset of disagreeable symptoms, using about 3 grains three times a day; then I gave about half the former dosage, and latterly the thyroid has been given once daily.

DR. A. JACOBI, New York—I desire to specially emphasize the probability of a correlation of the ductless glands. We are in the habit of generally attending to one, and not infrequently with an indifferent result. I believe that many of the failures of poor treatment are dependent on this, because I think it would be well, for practical reasons, to combine the extracts of several of these glands in insufficient or faulty development. In a number of instances in which I have done this the results have seemed to be better. In myxedema, however, thyroid feeding is usually sufficient. I wish also to direct attention to a point in the gross anatomy. We have been told in the paper that Virchow, fifty years ago, drew our attention to the condition of the base of the cranium—the shortening of the cranium observed in most cases of cretinism. This shortness is the result of early synchondrosis between the sphenoid and occipital bones. When a rachitis develops after birth and the bones become eburnated the limbs remain short; if rachitis runs its full course before birth there is calcification of the occipito-sphenoid synchondrosis before that time; hence the base of the cranium remains short, and this explains why the basal ganglia of the brain can not develop. This should not be lost sight of. I think it was Baillarger who first pointed that out, even before Virchow. What has been called fetal rachitis resembles myxedema more than it does rachitis; they are not the same histologically. We have been prone to forget this important fact in recent years. I was particularly interested when this subject was presented in 1853, and, hence, in 1857 I published a paper on ossification of the sutures and fontanelles of the cranium. Since that time I have seen a good many such cases, and have found that whether they are improved by thyroid or not, if the base of the cranium is short, the improvement will not be marked. I have in the hospital now a child of 6 years looking like a baby of 14 months. The fontanelle is four times the normal size, and all of the teeth are decayed. There is a large thyroid and a still larger thymus. There was no evidence of intellect until thyroid was given in very large doses. The child took first 2 grains, three times a day, of Welcome and Burrough's preparation, and the dose was gradually run up to 24 grains, three times a day. Then a little tachycardia and perspiration appeared, and the remedy was stopped for a few days, and resumed in the dose of 12 grains, three times daily. This dose has been taken for a long time; it is not an excessive dose in this case, because it does not give rise to bad symptoms; on the contrary, the patient is improving.

DR. DAVID RIESMAN, Philadelphia—In Philadelphia a large number of cases have been presented at society meetings in the last two or three years. I believe that more brilliant and tangible results are to be obtained from preventive medicine in this class of diseases than in any other. The reader of the paper has designated these conditions as congenital or acquired athyrea. If intended to imply a functional athyrea, the term is well chosen; but otherwise, not: for only in sporadic cases is the thyroid generally absent. But I take it that the author means to refer to a functional athyrea. With regard to achondroplasia, I would say that histologically it has nothing to do with rickets, nor is it identical with cretinism. One of the differential points is that in achondroplasia there is penetration of the periosteum inward, between the epiphysis and the diaphysis—a peculiar periosteal ingrowth, which is not seen in cretinism. There is also a sclerosis of the marrow of the diaphyses of the long bones in the former affection.

In connection with cretinism and achondroplasia, it is well to consider some other affections, such as infantilism, dwarfism, etc. We can not say that these are not all in some way related; and, from the practical standpoint, it seems to me advisable in all of them to give a trial to thyroid gland. It can do no harm if cautiously used, and may do good. If it does good, we are dealing with a cretinoid state, no matter what else may be present. In endemic cretinism, thyroid gland has not accomplished much. This would surprise us if we did not know the attending circumstances. The reasons are these: In the first place, the cause persists in endemic foci, whether in the water or in some other agent. Another cause of failure is that people are ignorant, and will not adopt such remedies as are for their own good. Fortunately endemic cretinism does not exist in this country, though a considerable number of cases have been reported from one part of Canada. Where it does exist, education will accomplish a great deal of good.

DR. ENGELMANN—Where the cases are brought under treatment late, there is almost always a hiatus left like that described by Dr. Shelly. In my case there has been a decided advance in growth on using the pituitary gland. When there is general mental and physical retrogression I make use of the thyroid in the morning and pituitary gland in the evening. In my case the only evidence of thyroidism observed was a rise of temperature, and as this caused the child no discomfort, the dose was not reduced. As to Dr. Riesman's criticism, it seems to me a very just one. I have in mind, however, another case in which the gland is very much enlarged and, on second thought, I will allow my name athyrea to stand for it and the former condition as well.

REPORT OF TWO CASES OF DERMOIDS IN CHILDREN:

ONE OF THE TESTICLE AND ONE OF THE OVARY: WITH NOTES ON THE INFREQUENCY OF THE FIRST: THE ORIGIN OF BOTH.*

SAMUEL W. KELLEY, M.D.
Professor of Diseases of Children, Cleveland College of Physicians and Surgeons; Pediatrist to the Cleveland General Hospital and to the City Hospital, Etc.
CLEVELAND, OHIO.

In this fragmentary paper I shall first deal with the infrequency of dermoids of the testicle, giving a list of cases hitherto reported; and will give secondly a résumé of the theories of the origin of dermoids; thirdly, the characteristics on which the diagnosis is based, and fourthly and lastly, reports of two cases, one of the testicle and one of the ovary.

CASES OF DERMOIDS OF TESTICLES HITHERTO REPORTED.

In 1885 Verneuil[1] published an analysis of nine cases, all he was able to find in the literature, to which he added one case observed by himself jointly with Mr. Paul Guersant. Dr. Theodore Kocher[2] refers to these ten cases of Verneuil and adds four more cases, which were all he was able to find; one each from Tilanus,[3] Geinitz[4] in Altenberg, Lang[5] in Innsbrück and Pitha and Bilroth.[6] Mr. Holmes (1869) refers to Verneuil's cases and then adds one from Dr. Van Buren[7] of New York. Mr. Curling states (1845) that "Dr. Duncan of Edinburg removed a congenital tumor of the testicle from a boy 8 years of age. Dr. Goodsir examined the tumor and found skin, hairs and portions of cartilage in it," and he mentions Erichsen's allusion to Mr. Marshall's case[8] (1852). I do not know whether these cases were among those known to Verneuil.

In 1886, D'Arcy Power[9] reported a case and exhibited before the London Pathological Society a specimen of a dermoid tumor of the testicle removed from a boy of 4 years. Power remarks that in the previous 200 years only ten cases had been recorded. Possibly he alludes to those collected by Verneuil. Manly[10] reported a case (in a man 61 years old) before the New York

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Diseases of Children, and approved for publication by the Executive Committee: Drs. Edwin Rosenthal, H. M. McClanahan and Samuel W. Kelley.

Academy of Medicine Feb. 14, 1899. C. C. Morris[11] reports a case of dermoid of the testicle removed by him from a boy of 12 years.

These are the only cases that a cursory look through the literature brought to my notice. There are probably others, but dermoids of the testicle certainly are not common, for Mr. Curling, with all his vast experience, writes as follows:[12] Cysts containing skin, hair, bone, teeth and other structures foreign to the part have, in some rare instances, been found in the scrotum in connection with the testicle. No case of the kind has fallen under my notice."

Senn says (1900): "There is no doubt that most of the cases of dermoid tumors of the testicle that have been reported were not within the testicle, but were on it—that is, were dermoids of the scrotum. That dermoids in this locality are not common is evident from the fact that Kocher[13] found only fourteen cases recorded in literature."

Ovarian dermoids are not nearly so rare as those of the testicle, but the reported cases are more numerous than we can reveiw to-day. However, ovariotomies at the seventh or eighth year have not been so frequent as to be without interest, and my case presented additional symptoms of obstruction of the bowels.

THEORIES OF THE ORIGIN OF DERMOIDS.

It is interesting to read in Guersant's "Surgical Diseases of Children," which was published in English no longer ago than 1871, the following statement: "In the newborn we sometimes, but quite rarely, meet with cysts in various parts of the body which contain the bones, teeth, hair and different portions of a fetus. These curious and familiar facts may be explained by the unequal development of two germs, one of which is encroached upon by the other, and remains, so to speak, nestled in it. They are sometimes for a very long time stationary, and in some cases terminate in inflammation." Thus dermoid cysts and fetal inclusions were confused. Again, in his chapter on cancer of the testicle, Guersant warns against confounding "these degenerated testicles with tumors produced by a false conception, sometimes seen in this region."

Holmes[14] writes (1869): "Dermoid tumors, when they occur in later life, are justly regarded as having no relation to fetal inclusion; but if one should be of congenital origin it might be difficult to distinguish it from an included fetal formation. Again, Mr. Holmes[15] writes: "The tumors of the testicle and scrotum met in children are almost all of a cancerous nature, or cystic, or included fetal remains. . . . Congenital dermoid cyst, or so-called fetal inclusion, is an affection very rarely met. . . . Teeth, bone and hair are the most common structures found in these cysts. As in those of the sacral region, . . . their real nature is doubtful. Some pathologists regard them as portions of a second fetus originally developed in the abdomen and following the testicle in its descent; others believe also in their fetal origin, but consider that they are originally developed in or near the testis; while the more general opinion at the present time seems to be that they bear more analogy to the dermoid cysts, such as are found so commonly in the orbit, than to cases of fetal inclusion. I incline to the latter view, founding my opinion partly on the analogy of such cases as that of Sir B. Brodie and Mr. Athol Johnson's, above referred to. In such cases tumors which arise congenitally are found, after death or removal, to contain scattered through their substance irregular masses of bone and other structures, but to present no evidence of any inclusion. The difficulty in the way of accepting this view of the congenital scrotal tumors is the occasional occurrence in them of structures (such as the gray matter of the brain in one case) which is ordinarily regarded as of too high organization to be produced by morbid action. Allowing, however, the accuracy of the observations, and admitting the fetal origin of such tumors as those which present compound tissue of this kind, we may still say that for the majority of congenital tumors in this region no different origin from that of the ordinary dermoid cysts has as yet been proved."

As you are well aware, the generally accepted opinion at the present day is that dermoids are caused, not by inclusion of one individual by another, but by disassociation or dislocation of some of the blastodermic elements of one individual; in other words, by an accidental malposition of a portion of one or more of the layers of the blastoderm, which took place during the developmental infolding of these various layers. These misplaced matrices developing produce specimens of their various structures—for instance, skin or mucous membrane, or epithelial cells (columnar, ciliated or squamous), hair follicles and consequently hair, sweat glands and their resultant secretions, teeth, bone, cartilage or nerve tissue; simple or more complex according to the nature of the embryonal elements that are displaced and intermingled. This places them in a class by themselves—the teratomata, distinguished from all other classes of tumors in which only one blastodermic layer is represented.

This theory of their origin also is supposed to account for the position in which dermoids are most often found, namely, where the different germinal layers fold in and coalesce, near the orbit, in the neck, in the coccygeal region, in the ovary, in the testicle or scrotum. Though they have been found in various other regions.

But now it seems that some embryologists claim that after impregnation of an ovum a single segmentation cell may split off before the establishment of the germ layers. And they say that it may be presumed as probable that almost up to the formation of the germinal layers any single segmentation cell even if dislocated, possesses the potentiality of producing all of the layers if necessary. So that if a cell of this kind were caught and infolded in the layers formed by the other cells it might proceed to develop into a parasitic growth of complex or organized structure.

In that case the difference in the origin of included fetus and of dermoid tumor would be that the former came from dissociated segmentation cell, while the latter was derived from a misplacement taking place after the formation of the layers.

In 1895 Max Wilms[16] published the results of careful and extensive studies, in which he claims that dermoids of the ovary are not teratomata, and are therefore not present congenitally; but that they are formed directly from an ovule in the ovary, by a kind of parthenogenesis. Kroemer's studies support the views of Wilms; and Kroemer shows that it is hardly proper to call the process parthenogenesis because, while this is a normal process in lower plant and animal life for the propagation of species, in the case in hand it is a pathologic process in which the growth and development of organs or portions of organs are atypical and without any definite law. Dr. Hans Arnsperger[17] agrees with Wilms and Kroemer, and they all take the view that the embryologic parts are formed from the ovule and the cystic parts from the follicle. Wilms explains dermoid

cysts of the testicle in somewhat the same manner, by a pathologic growth of the sperm cell. Wilms proposed the name "rudimentary parasites" or "embryomata" for encysted tumors and "embryoid tumors" for the solid variety.

B. Novy[18] announces after a series of microscopic studies, results virtually agreeing with the views of Wilms, who seems to be the first to have advanced proof of the ovulogenous theory. Dr. Francis Munch[19] gives an elaborate critical review of Wilms' work. After referring to the fact that dermoid cysts of the ovaries and testicles are distinguished from dermoid cysts occurring elsewhere, in that they are composed of three layers of the blastoderm, namely, the ectoderm, the endoderm and the mesoderm, Munch suggests the name of tridermic tumors as more appropriate than the name proposed by Wilms. He seems convinced that the theory of the parthenogenetic origin of these tumors so far as the ovary is concerned is well sustained, but that the exact similarity of those occurring in the testicles has not yet been definitely proven, although they are probably also of parthenogenetic origin.

This subject is very curious and fascinating, but let us take up something more practical and understandable.

THE CHARACTERISTICS OF DERMOIDS.

The characteristics on which the diagnosis clinically of dermoids is based are: the position, where the embryonal layers blend or of the testicle or ovary; the time of their appearance, which may be congenital or later. Of course, the beginnings of all dermoids, as of all teratomata, are present at birth and may be noticed then or they may not be discovered until later. According to Wilms these "rudimentary parasites" or "embryomata" of the testicle or ovary form an exception, or rather are put in a class separate from the teratomata. They are slow of growth and are painless unless inflamed. They may or may not fluctuate, according to whether they are cystic or solid, flaccid or tensely filled; or the same tumor may fluctuate in one part and be perfectly unyielding in another. Subcutaneous dermoids are not connected with the skin. They do not implicate adjacent glands unless inflamed or the seat of carcinomata.

It is to be remembered that sarcoma is the most common of the abdominal tumors found in childhood. That ovarian tumors in childhood are very rare; and when present are most apt to be dermoid cysts, carcinomata or teratomata. Also, that a dermoid may become the seat of carcinoma.

REPORTS OF TWO CASES. ONE OF THE TESTICLE AND ONE OF THE OVARY.

Case 1.—The first case I have to report is the following: Wm. T., aged 2½ years, was brought to me by his mother on account of a growth of the size of an English walnut in the situation of the left testicle. She was positive it had not been there at birth nor until he was a year old; but since appearing it had grown slowly, but steadily, notwithstanding they had used both internal medicines and local applications from several physicians. I found the tumor firm, the lower end being of a bony hardness and the upper portion, though fluctuating slightly, very tense. No pain, redness, tenderness, nor apparent heat. The scrotum was movable over it. The veins showed rather large and blue over its surface. There was no enlargement of adjacent lymphatics. Upon these data I based a diagnosis of a dermoid cyst, and advised its removal.

The parents consenting, I removed it in the presence of Drs. E. S. McIntosh and Alice M. Perry. The tumor corresponded anatomically to the testicle and did not involve any structure but the testicle. It was easily dissected out. Only the spermatic artery required tying. I closed the wound with catgut, and dressed with iodoform gauze. He made a good recovery, and is now a large, healthy boy, seven and one-half years after.

The tumor contained bone, fine hairs and several cavities filled with the sebaceous appearing material found in dermoids.

Case 2.—The other case I have to report is that of Elsie M., a girl of 7 years and 10 months. She is American born of German parents, who had six children, one of whom, the firstborn,

Fig. 1.—Dermoid of testicle. About one-half natural size.

was always sickly and died of "teething" at 16 months. Two children older and two younger than Elsie are now living and healthy. Elsie was small for her age, weighing 41½ pounds. (The average weight for girls at seven years is 48 pounds, at eight 52.9 pounds.) She appeared a rather pale and delicate, fair and flaxen-haired little girl, but bright and lively. When I was called to see her on June 11, 1900, they told me she had

Fig. 2.—Dermoid of ovary. About one-half natural size.

had no children's diseases but whooping cough when a babe and measles at 5 years of age. But that 2½ months previously she had been very sick with what had been called "inflammation of the bowels," with severe pain in the abdomen, some obstruction of the bowels, etc. During this sickness a "lump" was discovered in the region of the bladder. This was the first suspicion that the parents had of a tumor. She urinated frequently and urgently.

Seven weeks later she had suffered a second similar attack, which was severe for 4½ days, when it subsided rather promptly.

On my first examination, June 11, 1900, the tumor was easily palpable in the hypogastric region and seemed to be of the shape of a distended bladder. It extended nearly to the umbilicus, was dull on percussion, and firm, no fluctuation being made out. It was only slightly movable in its position. On catheterization I drew off ½ ounce of urine, of a strongly acid reaction. Evacuation of the urine made no difference in the tumor. On digital examination per rectum I found the uterus normal, but I could not satisfy myself about the ovaries. The tumor seemed to be at the fundus of the bladder.

June 18 I examined her again. The tumor was much more movable. I could press it upward till its upper margin was nearly an inch above the umbilicus and a space separated it from the os pubis, and could move it to either right or left of the middle line. On the previous day the child had had an attack of pain lasting about an hour. She had passed only about a pint of urine on the day of the pain, though she generally passed nearly a quart, it was said.

June 25 the tumor was much more freely movable than before. I could move it upward and to the left lumbar region freely—not so far to the right side. By this time I was pretty sure I had to deal with an ovarian tumor on the left side, and an exaggerated Trendelenburg position, massaged and manipulated the abdomen carefully and used a copious enema. These manœuvers were rewarded with a prompt relief of the pain and a free escape of feces and intestinal gases. That ended the attack of "inflammation of the bowels" and I believe my theory as to the cause of the obstruction was correct.

By this time the parents were convinced that the tumor must be removed. However, it was not until September that they would give final consent. On September 29 I operated on her at the Cleveland General Hospital, removing the tumor through a small median incision without any particular difficulty. It proved to be a dermoid cyst of the left ovary, of the size of an orange and consisting of a cyst containing fluid and a solid portion containing irregular-shaped pieces of cartilage, part of which is ossified, masses of atheromatous material and fine hairs.

The accompanying chart shows the progress of the case after operation. The slight rise of temperature in the second week was due to digestive disturbance merely, and was soon relieved. She made a fine recovery, went home two weeks after the operation, and has been well and has gone to school ever since.

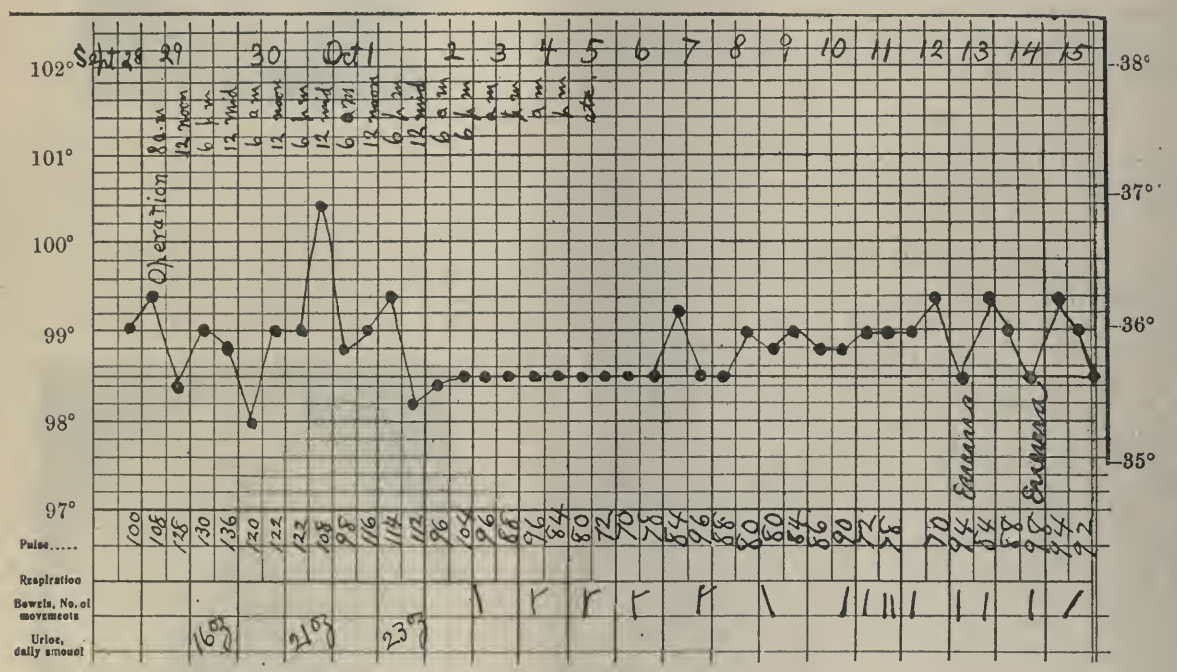

Figure 3.

probably a dermoid, and on July 9 I tried to get a skiagraph or a view with the fluoroscope in the hope of seeing teeth or bones, but without any satisfactory result.

I advised operation, but the parents refused, although I explained the possibility of danger from the supervention of malignancy, from purulent inflammation and resultant peritonitis which might be fatal or cause adhesions and render removal of the tumor more difficult later, from twisted pedicle, from obstruction of the bowels, or from pressure on the bladder. I gave her albuminate of iron, for she was rather anemic, and a mixture of acet. et citrate of potassium for the acid urine.

On July 23 I was summoned in alarm to see Elsie in what appeared to be the onset of another attack of "inflammation of the bowels," her parents said. I found her with extreme abdominal pain, worse in paroxysms, a quick pulse and partial obstruction of the bowels. They had given enemata and applied heat without any relief.

Aside from the ordinary causes of pain this might be caused by a twisted pedicle; but with the symptoms of obstruction I reasoned that probably a loop of intestine had slipped from behind the tumor and was imprisoned behind the tumor and between the tumor or its pedicle and the spine. So I placed the patient's body almost vertically with the head downward in

A STUDY OF THE CONTENTS OF THE VESICLES AND PUSTULES OF SMALLPOX.

A PRELIMINARY REPORT.*

JAY F. SCHAMBERG, M.D.

Professor of Diseases of the Skin in the Philadelphia Polyclinic and College for Graduates in Medicine; Assistant Physician to the Municipal Hospital for Infectious Diseases.

PHILADELPHIA.

Although we have convincing evidence that the *causa causans* of smallpox is contained in the purulent contents of the cutaneous lesions, the elusive micro-organism has thus far defied all efforts to establish its identity. The failure to discover the cause of variola has not been due to any inactivity on the part of investigators, for researches in this field have already given rise to a most extensive literature.

The bacteriologic investigation of smallpox is indissolubly associated with the study of the cause of vaccinia; according to the most authoritative opinion these two diseases have a common origin, and depend in all probability on the same causative agent.

HISTORICAL SUMMARY.

Sacco, in 1809, was the first to point out the presence in vaccine lymph of motile granules. Since this time scores of investigators have noted the presence of cocci of various kinds in vaccine lymph. In addition, larger round and oval bodies, not cultivable on ordinary media, have been described, first by Renault in 1881 and later by Guarnieri and others, and regarded by these observers as animal parasites. That bodies such as have been described exist both in vaccinal and variolous fluid is beyond contention. As in the case of the alleged cancer parasite the question is, are these bodies the result of cytoplasmic changes or are they in reality protozoa? Each side in this controversy has its array of champions, and the battle is being warmly waged.

Guarnieri and his school regard the vaccine and variolous bodies as sporozoa. Ferroni and Massari believe that they are derived from the nuclei of epithelial cells. Salmon states that the staining properties of the so-called parasites correspond in all respects with those exhibited by the nuclei of migratory leucocytes, and concludes after careful study that the pseudo-parasite is derived from this source. Ewing has recently declared that at least some of the vaccine corpuscles in human vascular tissues have their origin in degenerated and fragmented red blood cells. Whether or not these bodies bear any etiologic relationship to vaccinia and variola time and further study alone will determine.

It is pretty generally admitted that the micro-organisms in the fluid of vaccine and variolous lesions which are readily cultivable on ordinary media play no part in the production of these diseases. Klein and Copeman have independently found in vaccine and smallpox lesions a minute bacillus, which the latter observer has been able to grow on hens' eggs. Copeman's inoculation experiments with this organism are highly interesting, but as he himself admits they are as yet scarcely conclusive.

The preliminary work herewith presented is confined to a morphologic and cultural study of the contents of variolous vesicles and pustules.

THE TECHNIC OF THE PRESENT RESEARCH.

Cultures were made from 82 lesions in 51 cases of smallpox. The technic employed was as follows: The skin was washed with 95 per cent. alcohol and wiped dry with sterilized cotton; the vesicle or pustule was then transfixed with a two-edged lancet or a double-edged needle and one-half of the epidermal roof lifted up. A platinum loop was then inserted and a drop of the contents transferred to the culture tube. The earliest lesion cultured was a third-day vesicle. The investigator, who is familiar with smallpox and who has tried to obtain material for culture, knows how difficult it is in the early lesions to secure sufficient fluid to deposit on nutrient media. In unmodified smallpox with slow evolution of the efflorescence it is frequently impossible as late as the fourth day of the eruption to obtain a satisfactory amount of variolous lymph for culture purposes. On the other hand, in smallpox modified by vaccination one may at times secure pus from the lesions on the third day of the eruption. The writer was careful in cultivating early lesions to see that the platinum loop contained fluid and that this was properly placed on the media used for cultivation. The number of tubes inoculated was considerably in excess of 82, inasmuch as cultures were not infrequently made on three different media from the same pustule. The media employed were nutrient agar, glycerin agar, glucose agar, boullion, Loeffler's blood serum and coagulated egg albumin. The majority of the cultures were made on plain agar alone, but the other media were also freely employed. The tubes were incubated at a temperature of 37.5 C.

THE RESULTS.

Of the 82 lesions cultured 64 gave absolutely negative results, the culture tubes remaining perfecty free of growth of any kind. The remaining 18 tubes exhibited cultures presently to be described.

The age of the lesions from which cultures were taken is appended in tabular form. The day mentioned is the day of the eruption and not of the disease.

Third day	1 culture,	1 negative,	0 positive.
Fourth day	10 cultures,	10 negative,	0 positive.
Fifth day	12 cultures,	11 negative,	1 positive.
Sixth day	12 cultures,	12 negative,	0 positive.
Seventh day	13 cultures,	10 negative,	3 positive.
Eighth day	7 cultures.	5 negative,	2 positive.
Ninth day	13 cultures,	9 negative,	4 positive.
Tenth day	7 cultures,	4 negative,	3 positive.
Eleventh day.....	4 cultures,	2 negative,	2 positive.
Twelfth day.....	2 cultures,	0 negative,	2 positive.
Thirteenth day....	1 culture,	0 negative,	1 positive.
Total	82 cultures,	64 negative,	18 positive.

Of cultures made from lesions before the seventh day of the eruption 33 out of 34 proved to be sterile.

In 10 cultures the *Streptococcus pyogenes* alone was found.

In 2 cultures it was associated with a small bacillus resembling the diphtheria organism.

In 3 cases a small bacillus resembling the diphtheria bacillus was found.

In 2 cases the *Staphylococcus pyogenes aureus* was found alone, and in one more case associated with the streptococcus. On several occasions a growth was obtained from a pustule on one medium, for instance, bouillon, and negative cultures obtained on agar and blood serum. These cases have been classed with the positive cultures.

COMPARISON WITH THE WORK OF EWING AND BERGEY.

These results are in striking contrast with those recently obtained by Dr. James Ewing of New York, and embodied by him in a paper before the Association of American Physicians. He made cultures of the skin lesions in 23 cases of smallpox. In 17 he obtained the streptococcus in pure culture, in one case streptococcus

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Pathology and Physiology, and approved for publication by the Executive Committee: Drs. A. Stengel, Winfield S. Hall and Frank B. Wynn.

and *Staphylococcus pyogenes aureus,* in one streptococcus and a bacillus (Martin's bacillus?), and in a late lesion *Staphylococcus pyogenes aureus.* In one of the sterile cases streptococci were seen in sections of the skin. In other words, streptococci were found in 87 per cent. of the 23 cases examined. In my investigation, 77 per cent. of the cultures of 82 lesions remained sterile. I am at a complete loss to reconcile this discrepancy. I have in many cases deposited on the culture medium a large drop of yellowish creamy pus from a sixth, seventh or eighth day pustule and have failed to secure any growth from it. At the end of twenty-four or forty-eight hours the yellowish pus could still be seen, but no colonies were visible.

In view of the wide divergence in the findings obtained by Dr. Ewing and myself I have recently communicated with Dr. D. H. Bergey, first assistant in the laboratory of Hygiene of the University of Pennsylvania, to whom I had some months previously sent variolous lymph for certain investigations which he desired to carry out. This material was collected and sent in sealed sterilized capillary tubes. Only the largest pustules were selected in order to facilitate the gathering of the lymph, consequently the fluid represented late lesions, certainly not earlier than seventh-day pustules.

Fig. 1.—From fourth day smallpox vesicle. In Figures 1, 2, 3 and 4, "*a*" represents the so-called vaccine or variolous bodies. Each illustration is magnified 670 diameters.

Dr. Bergey has kindly permitted me to incorporate the results of his work in this paper. I quote that portion of his letter referring to the cultures:

The findings in each of the 12 cases examined are herewith given in detail:

CASE 1.—*Streptococcus pyogenes, Staphylococcus pyogenes aureus, Bacillus pseudo-diphtheria.*

CASE 2.—*Streptococcus pyogenes, Staphylococcus pyogenes aureus.*

CASE 3.—Cultures remained sterile.

CASE 4.—*Streptococcus pyogenes, Staphylococcus pyogenes aureus, Bacillus pseudo-diphtheria.*

CASE 5.—*Streptococcus pyogenes, Bacillus pseudo-diphtheria.*

CASES 6 and 7.—Cultures remained sterile.

CASE 8.—*Streptococcus pyogenes.*

CASES 9, 10, 11 and 12.—Cultures remained sterile.

It is seen from the above that of the 12 specimens of lymph examined 7 remained sterile. This would indicate a negative result in 58 per cent. of the examinations made. If the percentage of negative results in the seventh day and older lesions in my own series is computed it will be found to be 64 per cent.

Roger in his work on *"Les Maladies Infectieuses,"* page 456, says:

Frequently we have examined and cultured pus from variolous lesions without discovering any organism colorable or cultivable by present-day methods.

In well-marked cases of smallpox there frequently develops during the period of incrustation, about the twelfth to the fourteenth day, a number of flat blebs, a condition which may be appropriately called an impetigo variolosa. These blebs may result from direct conversion of variolous pustules into blisters, the lesions enlarging peripherally and the contents becoming thinned; or a reddish ring with raising up of the epidermis may form around the pustules and grow by peripheral extension. More infrequently blebs may form on healthy interpustular areas of skin. Under all these circumstances the affected pustules fill up with a watery dirty-yellow fluid which swarms with streptococci, diplococci and at times also bacilli. The fluid from a series of such lesions was inoculated on culture media. In every instance a growth was obtained in which streptococci were found in abundance. A small quantity of fluid from a large bleb was injected subcutaneously into the abdominal wall of a dog. In a few days there developed an egg-sized swelling apparently filled with a fluid material. A small bleb appeared on the surface of this swelling and rupturing left a dime-sized superficial ulceration. The tumefaction, however, subsided without breaking down, and the animal exhibited no further evidence of local or general disturbance.

Fig. 2.—From fifth day vaccination.

MICROSCOPIC EXAMINATIONS OF VARIOLOUS FLUID.

Smears of 15 vesicles and pustules were made and subjected to microscopic study. Lesions of different age from the fourth to the twelfth days were in this manner examined. Two smears of each lesion were prepared, the one being stained with Loeffler's methylene blue and the other with thionin. In addition some were stained with eosin-methylene-blue and with Gram's stain. It would occupy too much space to go into a detailed description of each slide. All of the preparations contained a considerable number of polymorphonuclear leucocytes and also mononuclear leucocytes. These were, of course, more abundant in the fully developed pustules. Eosinophiles were met with only in a few preparations. Nearly all the preparations showed more or less leucocytic degeneration. A number of large granular leucocytes without colorable nuclei were noted. Shreds of fibrin

were abundantly present in nearly all of the specimens. Bacteria were conspicuous by their absence. In some of the later lesions a few micrococci singly and in pairs were found on careful examination. On one or two occasions a few chains of short streptococci could also be discovered. The paucity of micro-organisms in the thick viscid pus was at first a source of considerable surprise. When cultures were made at a later date the explanation of this became evident.

Whenever the material in the pustules began to be converted into a watery substance; in other words, when pustulo-blebs began to form, the microscopic picture was at once changed. This fluid under the microscope was seen to swarm with myriads of streptococci, micrococci in pairs and not infrequently bacilli. This observation is of interest in view of the work of Sabouraud of Paris, who claims the streptococcus to be the cause of "impetigo contagiosa." The development of an extensive impetigo in the course of smallpox, by no means a rare complication, prolongs the convalescence and increases the liability to boils, abscesses, erysipelas and cutaneous gangrene. In a few cases the writer has seen death result directly from this extensive secondary involvement of the skin. Pus from a number of abscesses,

Fig. 3.—From sixth day smallpox vesicle.

boils and from several cases of cutaneous gangrene, all complicating smallpox, was examined and was seen to contain large numbers of streptococci, many in long chains.

In all of the preparations were found the so-called sporozoa described by Guarnieri and others. They were round or oval and varied in size from a large micrococcus to half the diameter of a red blood corpuscle. The average was perhaps four times the size of a staphylococcus. These bodies were found in leucocytes, but were for the most part free. Thionin stained them intensely, causing their contours to stand out in sharp relief. On coloring the bodies with Loeffler's methylene blue many of the larger ones were seen to be surrounded by a granular cell protoplasm. With both stains the coloration of these bodies was more intense than the nuclei of the leucocytes. It was noted, however, that the leucocytic nuclei did not stain in an entirely uniform manner, some being deeper in color than others and closely approaching the tint of the small round bodies. With eosin-methylene-blue these bodies did not stain differently than with Loeffler's blue. The Gram stain decolorized the bodies in the same manner as it did the nuclei of the leucocytes.

The fluid from several vaccinations was also examined and the same bodies found to be present. In fact, it would have been difficult under the microscope to distinguish between vaccinal and variolous fluid.

A thin watery fluid containing yellowish granules obtained from a fourteenth-day vaccination showed a considerable number of these bodies. This fluid inoculated on nutrient agar was proven to be perfectly sterile.

CONCLUSIONS.

The above results, it appears to me, justify the conclusion that the pustulation in smallpox is not due to secondary infection with any of the ordinary pyogenic germs, but is the result, in all probability, of the action of the micro-organism which produces the disease. Streptococci and other adventitious bacteria may be present in the late pustules, but occur only exceptionally in the early lesions. It is probable that the streptococcus plays an important part in the development of impetigo, boils, abscesses, erysipelas and gangrene which so commonly complicate smallpox.

I desire to acknowledge the valuable assistance rendered to me in carrying out this work by Drs. E. L. Graf and G. B. Walp, resident physicians at the Municipal Hospital, and Mr. J. B. Mencke, Jr., a medical student of the University of Pennsylvania.

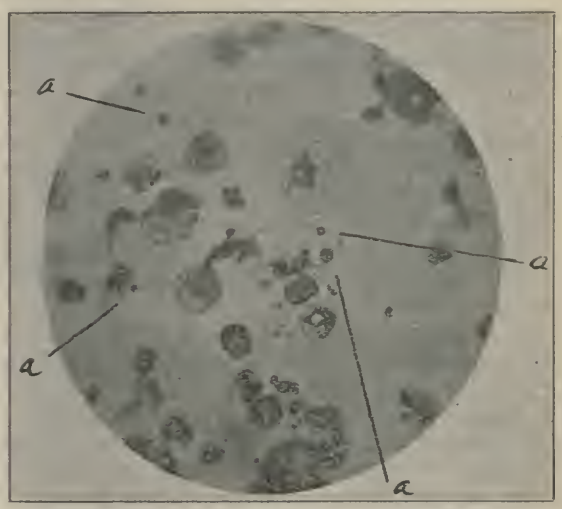

Fig. 4.—From fourteenth day vaccination.

DISCUSSION.

Dr. Louis C. Ager, Brooklyn—I would like to ask Dr. Schamberg if he thinks the small round bodies which so many think are the small cell nuclei differ in any marked respect from what we suppose to be the white cell nuclei in other forms of pus. We often find in pus the degeneration of leucocytes, apparently with free nuclei. Is there any marked difference between these conditions?

Dr. George Blumer, Albany, N. Y.—I heard Dr. Ewing's paper on this subject in Washington, and I was under the impression that his cases were all old postmortem cases, and that would account for the large number of streptococci present.

Dr. J. F. Schamberg, Philadelphia—I think my information is correct in regard to Dr. Ewing's findings, as the data were taken directly from a letter received from Dr. Ewing on this subject. I am aware that in addition to the work to which I have referred he reported having found streptococci in various organs; I have also found them in the heart, spleen and other organs at autopsy.

As to the nature of the so-called "variolous bodies," and as to their identity with granules resulting from leucocytic degeneration, that is the question to be solved. You will see from the photographs that some of these granules are ex-

tremely small, not exceeding in size the large micrococci commonly found on the skin.

DR. F. F. WESBROOK, Minneapolis—Are these bodies the same as those found in epithelioma?

DR. SCHAMBERG—Probably not.

POSTMORTEM EXAMINATIONS.*

W. D. HAINES, M.D.
CINCINNATI.

RESPONSIBILITIES OF MEDICOLEGAL EXAMINATIONS.

The legal aspect of postmortem examinations and reports of cases involving inheritance, crime and insurance entails responsibility second to none allotted to man in his relation to his fellow beings. The evidence elicited by medicolegal examination may very properly be regarded as the basis on which conviction or acquittal will rest in criminal cases, and the liberty or life of the defendant at bar, in many instances, is wholly in the hands of the pathologist.

Admitting the above propositions as true, the necessity of care, painstaking and thoroughness in the prosecution of this work is equally patent to physician and jurist. We are frequently asked, not only to ascertain the cause of death, but to actually fix responsibility for same. This is often difficult from the evidence at hand and occasionally impossible, although a succinct account of the antecedents of the injury is before us for investigation and analysis. Take, for example, the case of an individual who is a heavy drinker; the brain of such a subject is "watery" in life and has a marked tendency to rapid, extensive, fatal edema following injury. A blow that would cause little or no inconvenience to a well man may be followed by dire consequences in the alcoholic, and the fixing of moral and legal responsibility will annoy you not a little.

Death ensues occasionally during a physical examination of large uterine fibromata associated with inflammation of the pelvic veins, in the application of caustics to the faucial mucous membranes or after paracentesis. The situation is embarrassing in the extreme, nevertheless we must be honest with ourselves and admit that the examination, application and operation, like the blow which felled the alcoholic, were the exciting causes of death.

Persons dying suddenly with little or no history of deceased for a few days preceding death, are the most troublesome cases which confront the examiner. They are numerous in every large city, and the pathologic analysis will often tax to the utmost the acumen of the medical jurist. Unfortunately, the press and public assume in nine of every ten of the cases that some crime has been committed and the "sleuths" of the press, minions of the law and gossip of the vicinity where the corpse was found suffice to set the machinery of the coroner's office in motion. Thus we begin a legal inquiry into the cause of death, with a view to establishing the circumstances leading up to and fixing, if possible, the responsibility for same. The position in which the body lay when first discovered will assist us materially in determining the manner if not the actual cause of death.

POSTMORTEM STAINING.

In case the body has been moved postmortem staining, when present, if carefully studied, will elicit definite information. The position which the corpse occupied likewise throws a ray of light on cause of death. The under surface of the body becomes stained first, except where pressure had existed—call them "pressure points"—and these patches remain white in the Caucasian race, and sometimes exhibit images of objects on which the corpse had rested. Much importance is given to the presence and extent of livor mortis; it is one of the signs of death and is therefore of great value in differentiating cases of suspected death from suspended animation. Too much reliance, however, must not be placed on this sign, as there are trustworthy exceptions; the writer has seen this discoloration take place several hours prior to death in a case of gangrenous appendicitis with perforation.

Postmortem staining is prone to ensue soon after death in persons afflicted with arteriosclerosis; on the other hand, it is much delayed in subjects dead of long-continued, exhaustive disease or hemorrhage. It must be differentiated from ecchymosis following trauma; this may be done in the following manner: By incising the skin covering the parts and noting the condition of adjacent tissues. In ecchymosis we find diapedesis of red blood corpuscles, while in postmortem staining we find an exudation of serum and deeply congested condition of blood vessels in the immediate vicinity. Postmortem staining will change color and position in recent cases if the body be turned; it will remain stationary in ecchymotic discoloration, the variegated hues of ecchymosis lending material assistance in determining this point.

POSTMORTEM RIGIDITY.

Rigor mortis is an important feature in a medicolegal necropsy, in that it has a more or less definite relation to the cause of death and will assist in establishing the length of time which has elapsed since death ensued. We must ever bear in mind that the cause of death invariably modifies the time of appearance, extent and duration of this phase of evidence. It appears instantaneously in certain cases, is much delayed in others and so transitory at times as to entirely escape the attention of the examiner. It usually appears from two to fifteen hours after death and remains from twenty-four to thirty-six hours. Subjects dead of injury to the spinal cord, poisoning from large doses of arsenic or carbolic acid and those dying suddenly while in good physical condition become rigid soon after death; conversely, those dead of exhaustion, hemorrhage or shock will manifest no rigidity immediately after death; it will appear late, be slight and transitory.

Our physiologists are fond of referring in their reports to the condition of the heart at time of death. They say that the animal died in systole or diastole, and attach much importance to this incident; to the pathologist it signifies the presence or absence of postmortem rigidity in the heart muscle. Thus we rationally account for those peculiar phenomena of the cadaver which ever and anon excite the wonder and astonishment of the laity, persons found standing upright, resting against some object, riding on horseback and in the attitude of prayer though cold and rigid in death for many hours. While much has been written on this early and ever-constant postmortem change, extensive research is being made and valuable evidence may be had by a study of postmortem rigidity in any given case, it is singularly unfortunate that the one important forensic question, "At what time did death take place?" can not be answered by deductions drawn from this source. If asked by the court to testify as to the length of time which had

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Pathology and Physiology, and approved for publication by the Executive Committee: Drs. A. Stengel, Winfield S. Hall and Frank B. Wynn.

elapsed between death and the time of your examination experience admonishes great circumspection in your answer.

LATENT MENINGITIS.

The writer would like to accentuate the importance of latent meningitis. It exists in a large percentage of chronic alcoholics beyond middle life and is a prominent feature in every instance of sudden death when present. It is almost a daily occurrence for one of these old topers to get into a friendly scuffle with some younger person. He is pushed, thrown or falls down, and in falling strikes his head on some object: a scalp wound or a bloody nose is sustained; he walks, unassisted to a physician's office, his wound is dressed, he returns to his lodging, retires, becomes unconscious and is found dead next morning. The person with whom the deceased had a scuffle is apprehended by the police and a charge of manslaughter is placed opposite his name in the records. In your autopsy you will find adherent, thickened meninges studded with plaques of plastic lymph, subdural hemorrhage, edema of the brain, sclerotic, atheromatous and fatty degeneration of the organs throughout the body; a frail, disabled physiologic bark which a mere zephyr of adversity might waft into eternity. What shall we say of the moral and legal responsibility of the person who caused the fall which resulted in death? Is he guilty of this man's blood, or was he but the exciting cause of death? The courts have very properly ruled that he is not responsible for death in such cases. To be sure, we have had none of the classic symptoms of meningitis presenting during the life of our subject, and this fact admonishes us to employ the utmost care in conducting a medicolegal inquiry, for we are here dealing with a pathologic condition which is rarely or never diagnosticated during life and is only discovered on autopsy. We must look to the histologic conformation of the inflammatory deposit within the skull for an explanation of the singular discrepancy between cause and effect in such subjects. The arteries, ramifying the hyperplastic tissues of the membranes, are anomalous, in that they contain but two coats, the intima being absent, hence the ease with which transudation and hemorrhage may and does take place following injury.

SUICIDE BY CARBOLIC ACID.

Some years ago, in Cincinnati, a despondent prostitute in a fit of desperation swallowed a quantity of carbolic acid. Death was prompt and painless, since which time this has been adopted as the favorite method of the courtesan. The method is not wholly confined in its application to the lower world; occasionally some weary, soul-starved member of respectable society embraces this rapid, painless means of fleeing "to ills we know not of."

There have been 25 suicides reported to the coroner's office at Cincinnati the past year in which carbolic acid was the means selected to destroy life. This series may be divided into three classes with reference to time of death, viz.: those who die immediately, those who succumb in a few minutes and those who perish several hours later. The shortest time in which death followed was two minutes, the longest period was seventeen hours. The first division comprises the greatest number and the rationale of death is interesting to the medical jurist. The history of these cases after swallowing the fatal potion is short; they lapse into a state of somnolence in a minute or two from which they can not be aroused, death supervening a few minutes later.

The body stiffens quickly, postmortem staining appears at once and rapidly spreads over the entire surface of the body, the body temperature is slightly elevated and the time of its disappearance as compared with other cases is seemingly prolonged. A brown discoloration of the cornea with widely dilated pupils is frequently associated with death from carbolic acid poisoning. The skin about the mouth is usually discolored brown; this is caused by spilling the acid over the surface. The lips and tongue are of a peculiar white color, lending the effect, in appearance, of a mouth filled with cotton. Autopsy reveals but little, and this is only confirmatory evidence that would assist in determining the cause of death. The mucous membrane lining the esophagus and stomach is very white, eroded and easily removed by brushing. The kidneys, spleen, liver and lymph spaces are deeply congested.

DEATH BY INHIBITION.

It would be difficult, indeed, to render an intelligent verdict based solely on these meager data, but with the history of the patients having swallowed carbolic acid and remembering the neck as one of the "privileged" regions of the body, we readily see in the above account an illustration of Prof. Brown-Sequard's classic description of inhibition. The tendency of any strong irritant (and this applies to the therapeutic use of caustic applications) on the faucial surface, is toward inhibition, by its influence on the pneumogastric filaments distributed to the neck.

The writer has long held an opinion that death from chloroform occasionally results in the above manner. The anesthetizing of patients is often entrusted to students or non-medical persons. The jaw of the patient falls, his mouth is wide open, chloroform is poured too rapidly, a few drops find their way to the surface of the throat, the patient ceases breathing and expires at once.

Death from inhibition follows the lodgment of a bolus of food in the pharynx, notwithstanding the obstruction is quickly removed; again, slight blows, mere taps on the anterior surface of the neck, have caused instantaneous death. It has been observed that death from inhibition ensues most frequently when exposure follows soon after the ingestion of a full meal. Therefore, it is highly essential for the welfare of the patient that his stomach be emptied of all its contents by washing before administering an anesthetic. Sufficient data have not been obtained by the writer to speak authoritatively on the cause of death in the second and third divisions of the carbolic acid series—some die of shock, others of acute congestion of the kidney associated with dysuria and alteration or suppression of secretions in general. Our physicians are employing whisky as an antidote, with an encouraging measure of success in the treatment of cases which survive the initial shock.

IMPORTANCE OF KIDNEY LESIONS IN SUDDEN DEATH.

The kidney has been the most prolific source of death, from a medicolegal standpoint, in the writer's experience, this organ being the principal factor in probably 80 per cent. of all cases examined. The kidney is relatively large in infancy and youth, of definite proportion to body weight in adolescence and manhood, decreasing in size as age advances, becoming quite small in the aged.

Injurious substances introduced or deleterious products (toxins) generated within the body are more readily excreted by young persons than by the aged; an infection which would cause little or no discomfort in the young has been followed by death in older persons. Brouardel mentions an instance:

A market woman had a turkey left over; she invited a number of friends to help eat it; soon after the repast was finished all of those who had partaken of the turkey were seized with a sudden illness, the hostess succumbing. Examination of the dressing of the turkey revealed a substance resembling conicin; it was also found in the organs of the dead woman. It was not shown that this unfortunate woman ate more than the rest, but defective kidneys prevented rapid elimination of the poison and death ensued; the guests recovered.

Post-scarlatinous, puerperal and rheumatic nephritis exist in many persons who go about their daily avocations, unsuspected, until some accident befalls which demands for its relief increased activity on the part of the kidney, failure to respond resulting in death.

Practitioners are sometimes at a loss to account for the wide range and grave degree of mental symptoms in mild infections. Cases of influenza of seemingly mild type show an alarming array of mental symptoms. These are subjects of unsuspected nephritis and mortality is high in this class of patients.

In latent kidney disorders associated with heart disease it is sometimes impossible to say which affection should be given priority in time of appearance. For our purpose it matters little which began first, as inflammation of this organ is rarely followed by complete histologic recovery; functionally the kidney may be, to all appearance, working perfectly; let some disturbance occur which will markedly raise the interarterial pressure for any considerable time, an infection, for example, and the kidney becomes acutely congested, impeding circulation, increasing heart action, resulting in hypertrophy, and finally loss of compensation, dilatation, death. There are many certificates of death on file in our health department asserting edema of lungs to have been the cause of death, which, when carefully scrutinized, would appear to have been cases of desquamative nephritis. The pulmonary symptoms predominate in these cases and the lungs contain large quantities of frothy secretion similar to the lungs of persons dead of drowning. Coma is occasionally the first symptom of diabetes; gastrointestinal, convulsive and fulminating forms of kidney lesions will demand your attention in sudden deaths. A man is said to be as old as his arteries; it were more fitting to say, he is as old as his kidneys.

THE DIAGNOSIS OF CARCINOMA OF THE LARYNX.*

OTTO T. FREER, M.D.
CHICAGO.

(Concluded from p. 375.)

Tubercular tumors of the larynx resemble more papilloma or fibroma than carcinoma, as they are generally strictly circumscribed, smooth, with intact mucosa, broad-based or pedunculated and arise from the surface of the larynx in the manner of the benign growths. They may be covered with papillomata. In some cases, however, where the tumor is broad-based and diffuse, it may simulate carcinoma, as in the case reported by Gussenbauer, who extirpated a larynx supposing a tubercular tumor to be a malignant one. Hajek reports five cases of tubercular tumor of the larynx, all of which occurred after the fiftieth year, so that age is of little use in the diagnosis from carcinoma. Pulmonary tuberculosis is usually but not always present, so that the microscope may be needed for the diagnosis. The very rare association of carcinoma and tuberculosis in the larynx needs only to be mentioned.

The laryngeal affections of secondary syphilis can not well be mistaken for early carcinoma, but the tertiary forms of the disease may simulate it very closely.

While laryngeal tuberculosis is a very common disease authorities are agreed on the rarity of tertiary laryngeal syphilis. The forms likely to be hard to differentiate from early carcinoma are syphilitic gummatous infiltration and the true gummy tumor. The first resembles diffuse, the second circumscribed carcinoma. Though in most cases syphilitic infiltrations ulcerate early, quite often in resistant individuals they persist with unbroken surface or with but superficial ulceration for a long time. It is these forms that closely resemble the diffuse variety of carcinoma as shown in Figures 14 and 15. Diffuse gummy infiltration may involve only the mucosa or extend deeply into the muscles or perichondrium, hence often causes fixation of the vocal cord. It is especially apt to attack the epiglottis, but may involve the ventricular band, cords or a whole side or the entire interior of the larynx. The surface may be smooth or wrinkled, but does not usually present the nodular or warty excrescences due to carcinoma. The color is dusky red. In difficult cases inspection alone can not distinguish syphilitic infiltration from that of carcinoma.

Gummata of the larynx are a rare form of laryngeal syphilis. They form red, smooth, flat, circumscribed elevations covered with intact mucosa in the first part of their existence, and, according to Neumann, are more often multiple than single, being grouped on the anterior surface of the posterior pharyngeal wall, or on the epiglottis, ventricular bands or vocal cords. Their size may reach that of a pigeon's egg. They may interfere with the motions of the cord or arytenoid cartilages. The fact that they seldom inflame the tissues about them serves to differentiate them from growing carcinoma; in some cases, however, they are accompanied by diffuse reactive infiltration, inflammatory edema, and instead of their usual smoothness they may have a papillary surface. The most useful distinguishing quality possessed by the gumma before ulceration is its smooth, bright red, intact mucous covering which differs from the nodular irregular carcinomatous surface. As it softens the center of the gumma acquires a yellow hue.

In many cases of laryngeal syphilis it is not possible to get a luetic history, or the one obtained is so indistinct that it is rather misleading than enlightening. Confirmatory traces of the disease should therefore always be sought elsewhere, and it is important to inspect the pharynx and nose where other tertiary manifestations are often present. Iodid of potassium is our most valuable aid in diagnosis of syphilis from carcinoma, as a week of its use will usually bring vast improvement in syphilis. Some cases, however, are resistant to the drug, and many observers have seen temporary shrinkage of carcinoma under its use.

The rare condition called pachydermia laryngis by Virchow has usually a bilateral location over the processus vocales, a position very rarely the seat of carcinoma which may, however, originate in the pachydermatous tissue there. The elevation of pachydermia above the surface, the typical dovetailing of the thickened mass on one processus vocalis into the hollow of the opposite one make a confusion with carcinoma unlikely unless the papillæ of pachydermia be large enough to be macroscopically visible and the neighborhood of the swelling be roughened. As shown by Chiari in the report of a

---

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. J. F. Barnhill, C. R. Holmes and G. H. Makuen.

case of pachydermia of the floor of the ventricle which presented as a chalky white tumor on a red base, this affection in other than its typical location may cause errors in diagnosis. In Chiari's case laryngo-fissure was performed to remove the supposed carcinoma. Fibroma of the larynx when broad based and seated in the submucous tissues may be mistaken for carcinoma polypoides and the microscope may be needed for a de-

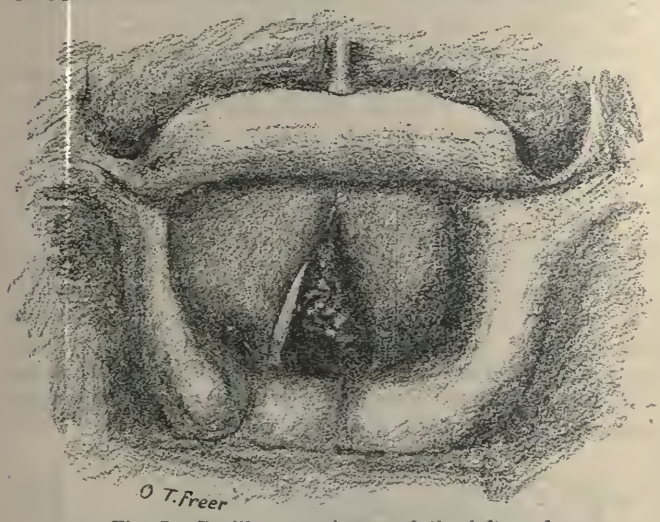

Fig. 7.—Papillary carcinoma of the left cord.

cision. Cysts, if deep seated, might cause doubt; ordinarily their translucence makes mistakes impossible. The benignant growths are distinguished from carcinoma by their seat on and not in the mucosa, by their very slow growth, absence of ulceration and inflammatory reaction. The mucous membrane covering them is usually normal in color and appearance.

The later stages of carcinoma of the larynx present more pronounced forms and the diagnosis as a rule be-

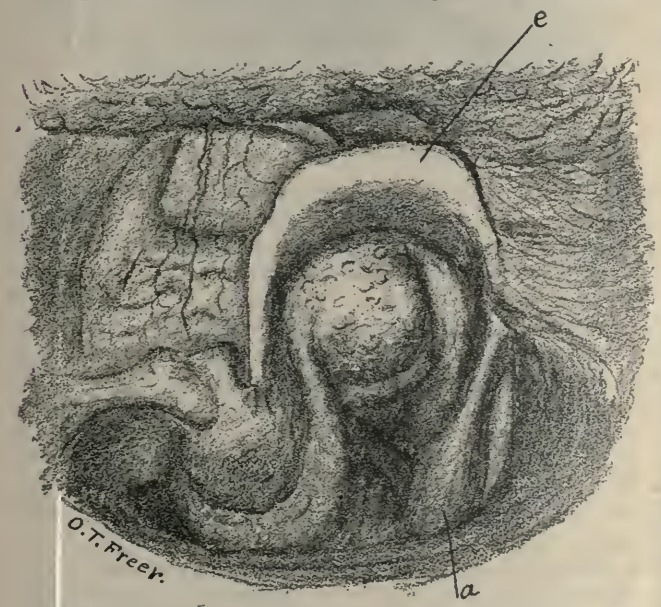

Fig. 2.—Diffuse carcinoma displacing larynx to the left. *e*, Epiglottis. *a*, Arytenoid cartilage.

comes easier. Carcinoma of the cord usually follows it to the anterior or posterior commissure and crosses over to the other cord forming the so-called circular carcinoma, as shown in Figure 5. The cords may thus become unwieldy, shapeless, nodular masses. On the ventricular bands a like circular course may be followed. Whatever its location in the larynx the spreading carcinoma usually causes chronic inflammatory reaction and edema in the invaded regions, creating monstrous swollen deformities of the arytenoid region, arytenoepiglottic folds and other parts. The assymmetry of these swellings is very characteristic, but they often hide the carcinomatous tissue partly or completely from view, as shown in Figure 7, where the edematous false cord permits a view of only a few sprouting excrescences of the tumor, a papillary carcinoma.

Ulceration seldom begins in carcinoma before a year has elapsed and in some forms it is absent. This is shown in Figure 2, where a large carcinoma has changed the entire laryngeal interior into a rigid, convoluted mass. Nowhere is ulceration visible. The right pharyngo-epiglottic fold is filled with the neoplasm and has pushed the entire larynx over to the left. At first, on account of the lack of ulceration in spite of its great size, the tumor impressed me as sarcoma, but micro-

Fig. 3.—External appearance of carcinoma shown in Fig. 2.

scopic examination of a piece showed it to be alveolar carcinoma. The age of the patient possessing this growth was 47 when it was first seen. The tumor had lasted eighteen months at this time. The symptoms began with hoarseness, to which the appearance of a large metastatic tumor in the right retro-maxillary region was soon added. The chief complaints were hoarseness, dysphagia and dyspnea. There has never been any pain or any stench to the breath. Tracheotomy became necessary and proved very difficult, as I had to enter the trachea just above the manubrium sterni on account of the situation of the tumor in the neck, which is shown in Figure 3, and which resulted from penetration of the carcinoma through the laryngeal skeleton. The patient's general health remained excellent for months until the increasing size of the tumor made swallowing impossible so that rectal feeding had to be resorted to.

The carcinoma shown in Figure 1, though large, also was not ulcerated.

The ulcerations of carcinoma arise from a neoplastic mass, new formation exceeding destruction as a rule, while the ulcer is apt to be filled with and surrounded by sprouting cauliflower protuberances of carcinomatous tissue. It is hard to tell where the ulcer ends and the intact epithelial surface begins. These characteristics of the carcinomatous ulcer are most often simulated by the ulcerations of syphilis and tuberculosis, which may offer great difficulties in diagnosis, as the granulation tissue they produce often forms tumor-like conditions and their histologic progress is really neoplastic in character. Usually, however, ulceration in these states so much exceeds new formation that doubt does not occur. The average syphilitic ulcer is deep, clean cut and crater-like, and has smooth, red, swollen borders, more like inflammatory than tumor tissue. Serpiginous and shallow ulcerations have likewise fairly sharp borders and smooth floors and impress the observer as seated on simple inflammatory infiltration. Doubt may be caused by ill-defined, superficial, granulating, syphilitic ulcers with massive, nodular infiltration underlying them and

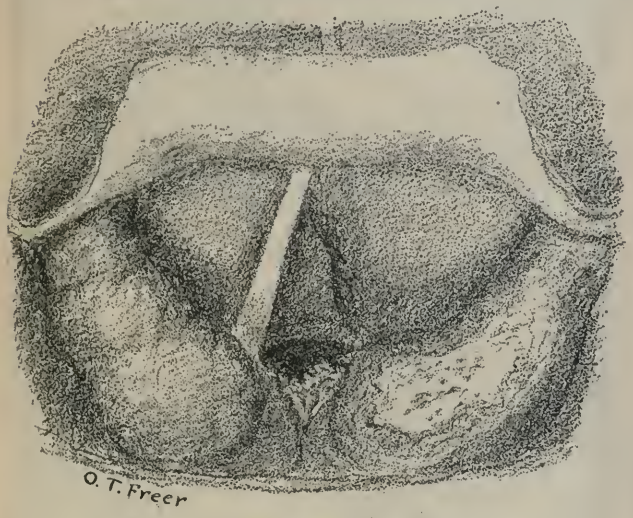

Fig. 14.—Tertiary syphilis of the larynx.

associated with immobilization of the arytenoid body. An example of this kind is shown in Figure 14. In this case the suspicion of carcinoma was removed by the discovery of a gumma of the clavicle.

Tubercular ulcers ordinarily are easier to distinguish from carcinoma than are those of syphilis. Frequently the ragged ulcerations, often seated on the cords, are purely destructive and have no infiltrated base. This type is commonly accompanied by such marked constitutional symptoms that mistake is impossible, and is characteristic of florid phthisis. A large ulcer of this sort that has destroyed the epiglottis is shown in Figure 12. The variety of tubercular ulcer accompanying the infiltrative kind of laryngeal tuberculosis leaves also little room for doubt, as the symmetrical chronic edemas of this form of disease do not resemble tumor formation. Even in this more chronic type pulmonary involvement is rarely absent and the purulent secretion of the ulcers contains numerous tubercle bacilli and may be swabbed off for examination.

Cicatrization of laryngeal carcinoma is regarded as a rare curiosity and serves to distinguish it from inveterate tertiary syphilis of the larynx, which is marked by a tendency to the formation of webs between the cords, stenosis due to cicatrices and cicatricial transformation of infiltrated submucous tissue, even where no ulceration has preceded. Carcinoma may, however, originate in syphilitic scars.

The last stage of carcinoma is that marked by perichondritis, perforation of the cartilages and extension to other parts beyond the larynx. This period is distinguished by suffocative dyspnea and often by otalgia, stench and dysphagia. The neoplasm may perforate the cartilages and appear externally early in the disease. This was the case in the carcinoma shown in Figures 7, 2, 10 and 5. In the latter the growth was found to have pierced the anterior junction of the thyroid cartilages after the larynx was removed. In the cases represented by Figures 7, 10 and 2 the tumor, after growing through the laryngeal skeleton, had transformed the larynx and upper part of the trachea into a hard, non-sensitive mass, that felt like a potato under the skin of the neck.

The external tumor is largely due to inflammatory thickening of the connective tissue under the sternohyoid and sterno-thyroid muscles caused by the advance of the carcinoma beyond the larynx, but it also contains varying amounts of the neoplasm. In the case shown in Figure 7 this fascial

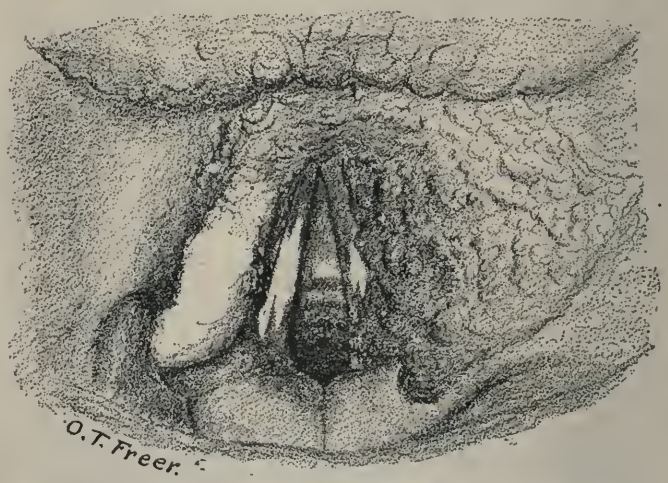

Fig. 12.—Destructive tubercular ulcer of the epiglottis.

inflammation had entered the sheath of the great vessels and compelled the late Dr. Christian Fenger to abandon laryngectomy already begun, as the larynx was united by a rigid mass to the vessels about it and could not be separated from them. The only things that these hard, usually painless external laryngeal tumors are likely to be confounded with are the swellings due to external perichondritis of the thyroid or cricoid cartilages. Such perichondritis may indeed be caused by carcinoma itself. Perichondritis phlegmons are painful often pit on pressure, later fluctuate and discharge pus. Their deep seat makes them feel like hard tumors in the beginning. Perichondritis is not uncommonly caused by carcinoma, but is also often due to syphilis and tuberculosis. It may involve the cricoid, arytenoid or thyroid cartilages, and is so closely simulated by inflammatory swellings or phlegmons of the submucous tissues that its existence should not be positively declared until it is proven by a view of the dead cartilage. The appearance, however, of pus welling up from an opening in a chronic inflammatory swelling in the larynx, especially in the region of the processus vocalis or anterior commissure, is almost proof of a necrosis of one of the cartilages. The great endolaryngeal swelling caused by perichondritis, especially that of

the thyroid or cricoid cartilages, may hide the syphilitic, tubercular, carcinomatous ulcer or other condition causing it so completely from view that a laryngoscopic diagnosis of the source of the perichondritis may be impossible for many weeks, and in some cases carcinoma thus hidden has not been found until a postmortem examination was made. The deep-seated inflammatory conditions so change the view of the laryngeal interior that the mirror often shows merely a confusion of edematous, translucent folds, the anatomical parts of the larynx being unrecognizable. The sudden appearance of a perichondritic abscess may be an early sign of a carcinoma that up to the time had been almost latent, so that the sudden and urgent dyspnea suggests an acute inflammatory condition rather than the chronic course of a malignant tumor.

Lymphatic involvement in intrinsic carcinoma is acknowledged by most authors to be usually late. Fraenkel states that in some patients who died of laryngeal carcinoma no localization was found in the lymphatic glands. Scheier's statistics show a large number of cases of the disease in which there were no lymphatic metastases. The fact that intrinsic carcinoma of the larynx so often remains local for a long time is an argu-

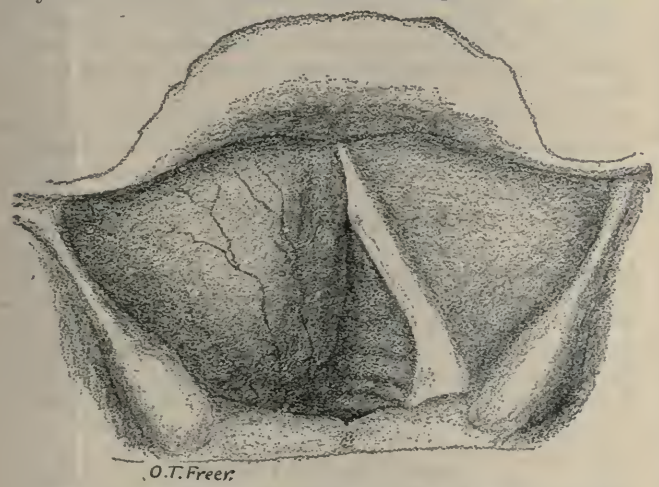

Fig. 9.—Angio-sarcoma of the right cord and ventricular band.

ment in favor of conservative and even endolaryngeal operations in early carcinomata of this order. In extrinsic carcinoma lymphatic involvement is usually much earlier and the spread of the tumor more rapid. An exception to this was presented by the carcinoma shown in Figure 1, which, in spite of large size, showed no infection of the lymphatic glands.

The diagnosis of carcinoma from sarcoma of the larynx may require the microscope. The localizations of sarcoma are the same as those of carcinoma, and the cords are also favorite seats. The tumor is generally better defined than carcinoma, has almost always a smooth surface and shows almost no tendency to ulcerate or create inflammatory reaction or edema. The painful swallowing, otalgia and stench of the later stages of carcinoma are absent. Dyspnea in time becomes a marked feature. The tumor as viewed laryngoscopically shows usually a covering of normal or hyperemic mucosa, while branching vessels may be seen traversing its surface. It may present convolutions and sulci. The deep congestion, ulceration and cauliflower excrescences of late carcinoma are absent, perichondritis and necrosis of the cartilages very rare. Sarcoma, like carcinoma, is commonest between the fortieth and fiftieth year, but more apt to occur in the earlier decades than carcinoma. Figure 9 shows an angiosarcoma occurring in the larynx of a woman of 25. Hoarseness was the only symptom for two and a half years before the patient came to me in May, 1901.

Her case had been declared tubercular a year before, thus illustrating the difficulties of diagnosis by inspection. A piece was removed with difficulty from the tough tumor with the Landgraf-Krause double curette, and proved to be angiosarcoma. I removed the tumor later by laryngotomy, and it was found that the cord and ventricular band had merged into its substance.

The foregoing has shown how difficult and even impossible may be the diagnosis of carcinoma of the larynx merely from the symptoms and by inspection. For this reason it is necessary in many cases to remove a piece of tumor for microscopic examination. This procedure has been opposed on the ground that it favored autoinfection with carcinoma elements, stimulated the growth of the neoplasm and led to errors in diagnosis. As the carcinoma cells are in intimate contact with the blood and lymph vessels and may readily enter these channels when the latter are intact, it seems unreasonable to consider the slight additional risk incurred by opening a few of them when the patient's life depends on a prompt and accurate diagnosis. An increase of glandular infection after test incisions is not mentioned in the literature, as it would be were it a usual or striking occurrence.

Chiari in 28 excisions for microscopic diagnosis only once saw more rapid growth of the tumor. As radical operation usually follows the diagnosis as soon as possible, added rate of growth is not a matter of much moment.

A positive microscopic test is conclusive if properly performed; that is, with the microtome sections vertically to the surface of the fragment of tumor. A negative result should, in most cases, lead to further excisions until the diagnosis is certain.

Errors occur if the cutting forceps seize only the mucosa or papillomata on the surface or at the periphery of the tumor. For this reason a piece must be taken from its center and the instrument crowded in deeply. For this purpose I prefer the forceps of Scheinmann with its projecting beak. As my naked-eye diagnosis of carcinoma in the case shown in Figure 7 was doubted, I succeeded in removing several pieces of typical carcinoma tissue from underneath the swollen ventricular band with the Scheinmann forceps, though at the time none of the growth could be seen and I knew of its location merely from previous examination. For tough tumors the double curettes are better.

Chiari, Rice, Thacher, Gerhardt, Virchow, Semon, B. Fraenkel, Neumann, Ernst Schmidt and Hajek advocate the removal of a piece for microscopic diagnosis as indispensable in many cases in order to attain a positive diagnosis of laryngeal carcinoma. To discard the aid of the microscope in so important a matter would be a reversal to primitive methods and like dispensing with the search for the tubercle bacillus. On the other hand, to follow the microscopic findings blindly would be a mistaken course, as it may be impossible to obtain an unequivocal fragment for the microscope.

Laryngotomy for diagnostic purposes is advocated by John N. Mackenzie, who has thus suggested an important means of recognizing laryngeal carcinoma. It is suitable to all those cases where a tumor is suspected but invisible or too deep seated for the obtaining of a fragment, or where inflammatory swelling fills up the larynx. As the voice is usually hoarse or lost possibly

injury to it from laryngotomy need not be considered. It is to be hoped that laryngeal carcinoma will be recognized earlier than heretofore by physicians so that laryngotomies and endolaryngeal operations will take the place of the too frequent laryngectomies.

DISCUSSION.

DR. E. FLETCHER INGALS, Chicago—The paper furnishes points of diagnosis of great importance in the early recognition of malignant growths. If we are to accomplish anything by operative measures, the disease must be recognized early. I wish especially to commend the author's drawings and his plan of presenting them to us in duplicate photographs so that we may examine them while the paper is being read. The difficulties of diagnosis are very well illustrated in Figure 14, which, I confess, I should have mistaken for a typical case of tubercular laryngitis if the Doctor had not demonstrated that it was syphilis.

DR. ROBERT C. MYLES, New York City—As to the question of diagnosis of malignant growths, it is important first to ascertain whether the patient wants it for practical purposes or not. If the patient does not intend to submit to a radical operation, it is, I think, rather foolish to take out pieces for a microscopic examination. As to the question of naked-eye and microscopic diagnosis, I have been fooled in both ways. Cases have been said, on the one hand, to be malignant on naked-eye examination, and subsequent events have shown that they were not. I have had the same experience with the microscopic diagnosis. So there is an element of uncertainty. The only hope of cure is through early action, and if we will impress on the patient and the general practitioner the importance of early diagnosis and operation, our results will be better and we will have more to show in the way of permanent benefit.

DR. O. T. FREER—The question of removal of a portion of the growth for microscopic examination has a number of opponents, and some of the members in the last international congress in Paris objected to this procedure on the ground that the histologist so often returned a vague report and added to the uncertainty. Though this is not infrequently the case the great majority of authorities are agreed that usually the microscopic test is unequivocal and an indispensable resource. The arguments of those who claimed that cutting away portions of a benignant tumor for microscopic purposes might lead to a change to malignancy have been refuted by Semon, and this reason, therefore, need not deter from taking away a piece of a papilloma suspected to be possibly a carcinoma. Though the laryngologist may be sure of the diagnosis of carcinoma from gross appearances, he may need a microscopic test to convince the patient and sometimes a doubting consultant.

I have found that a great number of physicians regard the laryngoscope as an instrument for the use of the specialist, and when asked to inspect a larynx many are quite unable to even direct the light properly on the mirror. It is this widespread lack of laryngoscopic skill that is responsible for the advanced stage at which laryngeal carcinoma is almost always discovered. If seen early enough the disease may be even eradicated by endolaryngeal modes, as proven by B. Fraenkel, and at least earlier recognition of carcinoma of the larynx would spare many patients laryngectomy and enable them to get radical relief from laryngotomy or partial laryngectomy.

Special Article.

VACATION NOTES.

G. FRANK LYDSTON, M.D.
Professor of Genito-Urinary Surgery, Medical Department, State University of Illinois; Surgeon to St. Mary's Hospital.
CHICAGO.

(Concluded from page 381.)

5. MELBOURNE, VICTORIA.

No visitor to Australia should leave without seeing Melbourne. Victoria is justly proud of her capital city, and, despite the envious criticisms of Sydneyites—there is great rivalry between the two cities—there is much of interest and beauty in Melbourne.

The railway between Sydney and Melbourne is itself worthy of comment. The two sections of the road are owned respectively by the governments of New South Wales and Victoria, and are run by the people and for the people. The Victorian railway has 32 lines—mostly short ones. The road loses £300,000 annually, but the people are well satisfied, as they get the benefit of the outlay, and it is more than repaid by the commercial and agricultural advantages of the road. There has been drought for seven years in Australia, and the farmers have sorely needed relief. The government railway has done yeoman service in this direction. An annual reduction of £250,000 in freight tariffs and £80,000 in fares has been made for the benefit of the farmers. During the bad seasons the road transports stock to distant good grazing ground free of charge. Feed and produce are also carried free. When farmers

have been the victims of bush fires the government supplies them with seed for new crops. Victoria has a debt of £50,000, £39,000 of which is invested in her railways. The investment is deemed a good one, and, if need be, private capital would take the roads off the government's hands very quickly. The government gladly builds new lines where necessary to open up the country.

The rolling stock of the Australian railway system seems very light and frail in general, but the roadbed is the best I ever saw. It is so well ballasted that one can move about quite comfortably while traveling at a 50-mile clip. The sleeping cars are American built, but the day coaches are on the English compartment plan.

The scenery of South Australia along the railway is somewhat disappointing. It has much of beauty, but nothing of grandeur. The fruit trees were in bloom—think of a September spring—and recent showers had brightened up the landscape. Here and there a pretty cottage with an English hedge about it lent color to the scenery. Prosperous-appearing farms and ranches were abundant. Distant glimpses of the Blue Mountains—Australia's pride—were had. These mountains are blue indeed. No imagination there. A touch of the bizarre is added by flocks of black and white crows. Queer birds, but this is a land of queer things. Bears two feet long, the platypus, and parrots that come in flocks to destroy grain—these are all queer. Queerest of all is the placard that stares at you from all the dead walls and fences of Melbourne: "Directions for treating snake bite. Symptoms and results of snake bite." And then the placard sagely advises the victim not to get excited, as the poison never kills under three hours, and sometimes takes twenty-four hours. Which reminds me of Nélaton's advice—was it Nélaton's?—not to get excited if you accidentally cut the carotid, "for it takes two minutes for the patient to faint, three minutes for him to die, and a minute and a half is all you need to tie the artery." Ugh!

Melbourne is well laid out, and in this respect suggestive of some American cities. The streets are clean—which is decidedly not American—but, thank heaven, the city has some good restaurants, which brings her again close to the American heart. Like her rival, Sydney, Melbourne is notably lacking in negroes and Chinese. An occasional picturesque East Indian or Singalese alone relieves the white monotony. The Australian colonist, like his English cousin, is a bit insular and provincial. He is given to rude, open-mouthed staring at strangers, still, taken "by and at large" he is not a bad fellow, and, if he would only come to America and learn English, he would do very well. After one has been advised, be it ever so courteously, that "the wye to the 'ospital is through that gyte hup the street a bit" a few times, he yearns for the land where atrophy of the "H" center is not epidemic.

Melbourne has ample hospital facilities, but is not yet strictly up to date—indeed, she is not even "a good second" to Sydney. The principal hospital is the Melbourne. This was founded in 1846, and it looks it. The building is of brick and stone and is the worse for wear. The interior comports with the exterior, save in the case of the wings, built several years ago, which are a little more modern. The grounds are spacious, but not attractive. There is a large tennis court for the resident staff and attendants. The capacity of the hospital is 320 beds, 120 surgical, and 200 medical. There is a large training school, with 90 nurses in attendance.

The operating theaters, of which there are two, show a slight tendency to modernism, but it will take much white paint and numerous modern appliances to put them on an aseptic basis. There is no special operating room for pus cases. Distinctively septic cases are operated on in the same room as the minor surgical cases—in the old operating theater all classes of cases are taken—contagious included. The Melbourne is the only hospital in the city which is open to the latter class. There are three tents devoted to contagious cases—men, women and children. This is all that Melbourne, with nearly 500,000 inhabitants, has to offer for the care of contagious diseases. There is a single tent with only five cots for the diphtheria cases. Two hundred and thirty cases were treated in this small diphtheria ward last year. Tracheotomy was performed on 20 of these for the relief of urgent symptoms, and of these 9 died. Intubation was performed on 33, and there were 21 deaths in all. Sixteen cases of scarlet fever, 75 measles, and numerous cases of septic poisoning of various kinds were treated in the tents. Many cases of scarlet fever, measles and diphtheria were refused admission for want of accommodation.

The city is building a £25,000 contagious disease hospital, but, for lack of £2,000 to complete it, no work has been done on it for two years. This shows a public spirit worthy of a New York. The surgeon in charge at the Melbourne, however, says he can do more work with his tents than in buildings twice their size. A new and commodious deadhouse shows that the Melbourne Hospital tries to finish well. This has excellent facilities for students doing special autopsy work, and a small private lecture hall.

That the Melbourne Hospital has a field for its work is shown by its census of last year. Nearly 5,000 in-patients and nearly 18,000 out-patients were cared for. The surgical operations numbered 1,566. The hospital has a large amphitheater for clinical teaching. About 160 students were in attendance at the time of my visit. They were mostly from Melbourne University. None of the hospitals, however, are appendages of a medical college.

The status of appendicitis at the Melbourne Hospital is unexceptionable. Early operation is the keynote. Radicalism is the war cry. The suprapubic operation for stone is in vogue. Keegan, Freyer, *et al*, do not seem to have done any missionary work here. The prostate is not often attacked and when it is, the suprapubic method is used. I, of course, again said a good word for the perineal route. Palliation is more popular in Melbourne than it should be, but, as with us, is often adopted because of circumstances over which the surgeon has no control.

There is no obstetrical department at the Melbourne. Such cases are sent to the Women's and Maternity Hospital. This institution attends a large number of obstetrical cases yearly, and has about 40 beds in its gynecologic department. The other hospitals are the Alfred and the St. Vincent's. The nomenclature of these is patterned after the Sydney hospitals—indeed, St. Vincent's is a branch of the Sydney hospital of the same name. Alfred Hospital has a capacity of about 180 and is very modern in its appointments, but will not enjoy the distinction long, for St. Vincent's small building is to be replaced by a modern 300 bed hospital, built and furnished on strictly American lines. This is the ideal and nobody knows it better than the Australian.

There is a small special eye and ear infirmary and a special hospital for children. Melbourne has had no epidemic of plague. Two cases developed during the Sydney epidemic, that was all. Melbournites say they have no plague because they are cleaner than Sydney. To which the Sydneyites, in the true scientific, not in the vulgar sense, cry "rats!"

In passing I wish to remark that the persons who chew tobacco, or are catarrhally inclined, would best not visit Australia. The rigid enforcement of the anti-spitting law has evolved a new race of beings who never expectorate. This has driven the cuspidor out of business. Look where you will, in hotel corridor, restaurants, public buildings, and in your own room, you will find it not. The warning placard is now superfluous, although still in evidence.

The scarcity of water in Australia has impelled the authorities to direct the people to take shower baths only. The tub bath is tabooed. Perchance the bathtub may follow the cuspidor. Evolution works wonders. Whatever the explanation of the scarcity of the "expectoroon," Australia would seem to be no place for throat specialists or their patients.

In operating near the female bladder it must be remembered that the latter is never perceptible to the touch unless distended, or, better still, unless an instrument such as a sound has been passed into it.—*Toledo Med. and Surg. Reporter.*

SATURDAY, FEBRUARY 14, 1903.

THE SURGICAL TREATMENT OF OLD EMPYEMATA.

Nearly all physicians have come to recognize that the presence of pus in the pleural cavity is generally a definite indication for immediate operation, and a large percentage of rapid recoveries and complete cures has become the rule in such cases. We recently noticed a method[1] that has been successfully used by Dr. E. Fletcher Ingals in these cases, and which is available to the general practitioner without surgical assistance. In the great majority of cases this conservative operation is all that is required and cases go on readily to recovery.

Neglected cases are still occasionally met, however, in which the purulent exudate has been allowed to compress the lung for so long a time that the visceral pleura has become so much thickened and so inelastic that expansion of the lung is impossible, even after evacuation of the pus. Operation offers the only method of successfully dealing with these cases. While fortunately rare, such cases are frequent enough so that all surgeons of extensive practice are occasionally called on to treat them, and their successful management has been one of the most difficult problems in surgery. Three methods have been used with more or less success. Estlander of Helsingfors, Finland, was the first to bring about a cure in these cases by resecting a large number of ribs, thus permitting the chest wall to collapse and close the cavity existing between the permanently contracted lung and the parietal pleura. Finding that even after extensive resection of the ribs, as suggested by Estlander, the thickened parietal pleura sometimes prevented falling in of the chest wall, Schede of Bonn combined extensive excision of the parietal pleura with excision of the ribs, and this method has proved a satisfactory means of dealing with the obstinate cases which do not yield to the simpler procedure of Estlander.

George R. Fowler[2] of Brooklyn first attempted to obliterate these cavities, not by permitting collapse of the chest wall, but by providing for the expansion of the contracted lung. He succeeded in stripping off the very much thickened layer of visceral pleura, thus permitting the lung to expand and obliterate the cavity. Whenever it is possible to perform this operation the lung partly or entirely resumes its function and the deformity from extensive resection of the chest wall is avoided; advantages sufficiently great to make this the operation of choice in suitable cases. In foreign literature this procedure is generally referred to as Delorme's operation, credit for priority being given to the French surgeon on the basis of a report of some experiments on the cadaver which he presented before the French Surgical Congress in April, 1893. Fowler operated, however, entirely without knowledge of Delorme's experimental operation of a somewhat similar character, and as the first to successfully demonstrate its feasibility on the living human being he undoubtedly deserves the credit for priority. Delorme did not perform the operation until some time after Fowler's successful operation.

Since Delorme's publication decortication of the lung seems to have become generally recognized by European surgeons as a valuable method of dealing with these cases, but it is apparently seldom employed in this country, the only paper besides that of Fowler being by Ferguson[3] of Chicago. At the last French Surgical Congress the operation was introduced for discussion by Gangolphe[4] of Lyons. He reported two cases of chronic empyema, one of which had lasted three and a half years, the other six and a half years, both of which were successfully operated on, although secondary resection of some ribs was necessary to complete the cure in one of the cases. Statistical studies by Kurpjuweit,[5] who reports five cases from Garré's Clinic at Königsburg and has collected 56 cases from the literature, show 35.7 per cent. of complete recoveries, 19.7 per cent. improved, 33.9 per cent. unimproved and a mortality of 10.7 per cent. Comparing the results of decortication with extensive resections of the ribs we find that the latter operation gives 56.3 per cent. of cures, 20 per cent. improved, 3 per cent. unimproved and a mortality of 20 per cent. Although the percentage of permanent cures after decortication is not so great as after Estlander's or Schede's operations, 56.3 per cent. as compared with 35.7 per cent. in favor of extensive rib resections, the smaller mortality and the possibility of expansion and more or less complete resumption of function of the lung and the avoidance of extensive deformity are important factors which can not be disregarded in favor of decortication. That the function of the lung is regained to a very great extent is shown in at least one case which has been reported in which a patient recovered from a severe pneumonia of his sound lung by the aid of a crippled lung which had been partly restored to its function by decortication.

If all cases of empyema were treated by early and free drainage extensive operations of all kinds would prove unnecessary, but as long as physicians fail to recognize the very evident physical signs of this condition and neglect the use of an aspirating needle, such cases will continue to be overlooked. The operation of decortication of the lung, devised by an American surgeon and shown to be an efficient means of treatment of these cases seems worthy of more attention than it has thus far received by surgeons in this country.

RHEUMATOID ARTHRITIS: A THREE-DISEASE GROUP.

Probably nothing did more to remove some of the mystery and the opprobrium of ignorance that attach to many so-called rheumatic affections than the acceptance of the doctrine of a disease bearing certain relations to gout and rheumatism, but absolutely distinct from either. To this, at first, for want of a better, the name rheumatic gout was given. Later the terms rheumatoid arthritis and arthritis deformans came into use, the luxuriance of nomenclature, as in so many other cases, bearing a direct ratio to our lack of knowledge of the affection. Much of the progress with regard to this disease is due to English clinicians for special observations of the greatest practical value. It is of more than ordinary interest, then, to find that a number of the English authorities on this class of diseases are now pretty well agreed that under the name arthritis deformans at least two and probably three diseases distinct from one another exist.

Dr. Bannatyne[1] gave definite expression to the opinion that the rheumatoid arthritis group contains three perfectly distinct joint affections. These are, first, the pathologic condition commonly confined to the hip joint, seen rarely in any but elderly men, and consequently very properly spoken of as senile osteo-arthritis. Second, the affection met more frequently among women about middle life, the symptomatic course usually beginning by bony enlargements in the terminal joints of the fingers and in the carpo-metacarpal joint of the thumb. Thirdly, there is the class of cases which occurs mostly in women who are seldom much over 20, the first symptom being a tumefaction of the proximal phalangeal joints. The swelling in these cases, however, often becomes noticeable in the wrist early in the disease. The characteristics of the affection are its acuteness, its distinctly symmetrical character and the fact that the swelling extends well beyond the affected joints so that, for instance, the fingers take on a fusiform appearance.

The first form of the disease has been recognized by medical men generally as a more or less distinct pathologic entity for some time. The second form, beginning in the terminal finger joints, is by no means infrequent. In its preliminary stages it is often considered of little significance, being spoken of as Heberden's nodes. It may give no serious symptoms for many years, but the deformity may eventually become considerable, the bony outgrowth characteristic of the disease spreading to many joints and the patient, usually a woman, becoming a helpless cripple. The symptoms are never acute, however, and there is never any temperature. In the third form of the disease, acuity is the prominent feature. The disease begins with pain, swelling and redness, the temperature rises every day to above 100, and may reach 102. The febrile course continues for three or four weeks, when by self-limitation that suggests the infectious nature of the ailment the temperature sinks to normal, though the pulse does not become normal for a considerable period later. Marked immobility, deformity and muscular atrophy remain after the attack is over and the patients are often chronic invalids. Recurrences are almost the rule, and each attack leaves the patient permanently a little worse off than before. For this form of rheumatoid arthritis Dr. Garrod has suggested the name acute rheumatoid arthritis, which is fairly descriptive and seems to deserve a place in the permanent literature of the subject.

At the meeting of the British Medical Association in 1901, Dr. Garrod advanced the opinion that the only way to make our knowledge of these varieties of disease definite was to admit the existence of these three forms and look for the results of autopsies to confirm the clinical distinction.

Dr. W. Hale White,[2] in the last volume of Guy's Hospital reports, gives the results of an autopsy on a case of acute rheumatoid arthritis, the first, we believe, that has been made with the definite purpose of locating the exact lesions present in this disease. The pathologic changes consist in a chronic inflammation of the synovial membrane, together with a thickening of the tissues outside of the joints. Perforations of the cartilages were found, but were traceable to the pressure of the thickened synovial membranes. Changes in the bones were also secondary to the irritation of the redundant synovia. There was nothing like bony or cartilaginous outgrowths present. From the synovial fluid a coccus was cultivated, growing at times in pairs, never in chains. Dr. Bannatyne, in a similar case, found a short bacillus that stained especially at both ends and so resembled at times a diplococcus. While these studies do not definitely settle the existence of three distinct diseases in the arthritis deformans group, they do furnish an excellent basis on which to found further investigations of an interesting and important medical question, for which opportunities are not lacking here in America.

UP-TO-DATE JOURNALS.

There is an unfortunate practice—we do not know how far it is unavoidable—of certain medical journals appearing later than their advertised time and yet having nothing on their pages to show the exact date of appearance. We have in mind one otherwise excellent journal which habitually appears about three months late, the October number usually appearing in January, and so on through the year. This is, in one sense of the word, an imposition on its readers, and is more important when one comes to consult files of some years back. For instance, if a journal has an article giving an account of something new, some new discovery of importance, very serious questions of priority might arise, and unless the fact of the delayed appearance were generally known, injustice be done. An article published in a journal dated three months or even one month earlier than its actual appearance might get the credit of priority undeservedly. Such things have happened in the past, and are of more serious conse-

quence than perhaps at first appears. Another questionable procedure is that of certain high-class publications which appear more or less irregularly and do not have the exact date of their appearance anywhere in their pages. A reform in this matter would also be advisable.

JOURNALISTIC NOTES.

The *Interstate Medical Journal* introduces a valuable feature with its January issue. The whole number is devoted to a review of the medical literature of the year 1902, each department being under the direction of a specialist. In this way it forms a brief but convenient and fairly full statement of the principal progress that has been made during the year. This is to be a feature of the journal hereafter, each January issue containing an epitome of the medical and surgical progress of the preceding twelve months. The *Journal of Cutaneous and Genito-urinary Diseases* will hereafter appear under a new title, the *Journal of Cutaneous Diseases, Including Syphilis,* under the management of Dr. A. D. Mewborn of New York. The old association with genito-urinary diseases which, the editor remarks, were in no way related to dermatology, has been dropped. The syphilodermata belong to dermatology and have no relation with genito-urinary surgery. Syphilis should be considered as truly a dermatosis as leprosy or skin tuberculosis. It will be seen that the scope of the journal is somewhat narrowed, but its usefulness will be in no way diminished and the specialty of dermatology is certainly large enough to support a first-class organ in this country.

MEDICAL ADVERTISEMENTS AND THE RELIGIOUS PRESS.

THE JOURNAL has had occasion to note the carelessness, to use no worse term, of religious journals as to the character of their advertisements. It is a pleasure to notice that in some quarters at least this is no longer to be the case. There are nine official journals of the Methodist church, the advertising pages of which are all under one management, and the announcement is made—as we see by the *Medical Standard*—that after Jan. 1, 1903, no medical advertisements of any character will be accepted, and that only such contracts as are at present in force will be carried out, and then not renewed on any terms The enforcement of this rule will clear these journals of whatever share of reproach they may have before deserved; they have not been the worst examples of such reprehensible advertising, as we have had occasion to notice in the past. It is to be hoped that other religious journals will follow this example and clear their advertising pages of what is in direct opposition to the teachings of their editorial pages, in spirit if not exactly in letter. As the advertising agent of the Methodist journals says, it may be a financial loss for the time being, but his opinion that the advertisers that are accepted will profit by it and in time make up for the loss is, we believe, a correct one. The journal which is careful in its advertisements gives at once a recommendation to whatever it advertises. This should be especially the case with the religious journals.

LESIONS OF THE PANCREAS ASSOCIATED WITH CIRRHOSIS OF THE LIVER.

By reason of the part played by the liver in carbohydrate-metabolism glycosuria developing in the course of diseases of that viscus has been attributed to derangement of its function. Such a result, it was thought, is due to the entrance of the metabolic products directly into the general circulation, instead of passing through the liver, whose portal vessels are obstructed in consequence of the morbid process present. When it was shown that cirrhosis of the liver is but rarely attended with dextrosuria, it was suggested that the appearance of sugar in the urine under such circumstances is due to failure on the part of the liver cells, by reason of the existing disease, to retain the sugar brought to them. It was, however, found that glycosuria developed at times in the absence of disease of the liver and failed at other times to develop notwithstanding the presence of such disease. More recently, however, disease of the pancreas has been held responsible for the glycosuria, and it has been found that it is especially lesions of the islands of Langerhans that are associated with that condition. In some cases interstitial hepatitis has been found together with interstitial pancreatitis. With the object of reaching a definitive opinion in the matter, Dr. F. Steinhaus[1] undertook an anatomic study of 12 fatal cases of cirrhosis of the liver. Six of these were of perilobular type, 1 was associated with malignant adenoma or adenocarcinoma, 1 was probably syphilitic, 3 were cases of diffuse subacute interstitial hepatitis and 1 was an example of typical portal cirrhosis. In all, with the exception of the last, there was found distinct inflammatory hyperplasia of the interstitial tissue of the pancreas, exhibiting various points of correspondence with the inflammatory process in the liver. The changes consisted in cirrhosis, partly perilobular and partly periacinous, in the most marked degree associated with considerable destruction of glandular parenchyma. Inasmuch as foci of small-cell lymphocytic infiltration also were present, together with hyperplasia of blood capillaries and pancreatic ducts, the process may be designated an interstitial pancreatitis in the same sense as the term interstitial hepatitis is used. The islands of Langerhans were unchanged in structure in 11 of the 12 cases in which they were examined. As in cases of true diabetes associated with cirrhosis of the liver, whether attended with hemochromatosis or not, the demonstrable severe disease of the pancreas renders it probable that not the disease of the liver, but rather that of the pancreas, is of paramount significance, so from the results of the investigations under consideration the reduction in the limits of tolerance for sugar on the part of patients suffering from cirrhosis of the liver may be attributed to changes in the pancreas. The fact that diabetes does not develop in all cases of cirrhosis of the liver is to be interpreted from experimental observations as indicating that the pancreas under such circumstances still possesses relatively sufficient functionally active tissue to prevent the development of diabetes. Accordingly, it appears as little necessary to differentiate the glycosuria attending cirrhosis of the liver from pan-

1. Deutsches Archiv für klinische Medicin, 74, B., 5 u. 6 H., p. 537.

creatic diabetes principally in accordance with its pathogenesis as to distinguish from pancreatic diabetes other forms of glycosuria for which recently the possibility of derangement of the function of the pancreas has been demonstrated (for instance, arteriosclerotic diabetes). Thus the grounds for a uniform conception of diabetes are increased. This will be manifested by the occurrence of diabetes mellitus, of whatever form, only in consequence of derangement in the function of the pancreas, and the fact that this organ alone subserves the function of consuming sugar in the metabolism of the organism.

Medical News.

CONNECTICUT.

Money for Hospital.—By the will of George Griffin of Derby, about $50,000 is available for the emergency hospital proposed for that city.

A whooping cough epidemic is reported in Norwich, with more than 500 cases. A strange popular error seems to exist that whooping cough is not a dangerous disease, notwithstanding the constant iteration of the fact that it causes more deaths than either measles or scarlet fever.

Tuberculosis Hospital Assured.—Gifts have been made to the New Haven County Anti-Tuberculosis Association sufficient to enable it to proceed with its plans. It is proposed to buy land on Woodbridge Heights, north of New Haven and thereon to erect three cottages of eight rooms each.

More December Deaths.—By mortality reports received there were 1,298 deaths during December. This was 215 more than in November, and 158 more than in December of last year, and 76 more than the average number of deaths in December for the five years preceding. The death rate per 1,000 was 17.5 for the large towns, for the small towns 16.0, and for the whole state 17.1. The deaths reported from infectious diseases, including diarrheal, were 230, or 17.7 per cent. of the total mortality.

Deaths of the Year.—The total deaths for 1902 was 14,376; 480 less than in 1901, and 1,992 less than in the year 1900, also 330 less than the average of the previous 10 years. When it is remembered that three of the most contagious and often the most fatal diseases, measles, scarlet fever and diphtheria, have each occurred in more than 100 of the 168 towns in the state, and that smallpox has been present in about one-fifth of the towns during the year, it is remarkable that the number of deaths has diminished rather than increased. The State Board of Health remarks:

> Two facts satisfactorily explain this unexpected condition: One is that all these maladies have appeared in an exceptionally mild type; the other is, that although these diseases are epidemic in character, the vigilance and intelligent supervision of the local health officers, and the willing co-operation of citizens, have kept them under better control than ever before. It is only a just tribute to the town health officers of Connecticut to assert that under their judicious and well-directed efforts they have saved hundreds of lives during the year.

DISTRICT OF COLUMBIA.

Hospital Bequests.—By the will of the late Frederick Pilling, at the death of his wife, $1,000 each is to be paid Garfield Hospital, Emergency Hospital, City Orphan Asylum, Associated Charities, and Huddlesfield Infirmary of Huddlesfield, England.

Health of the District.—The report of the health officer for the week ended January 31 shows the total number of deaths to have been 135, of which 67 were white and 68 colored. During the week there developed 22 cases of typhoid fever, 3 of scarlet fever, 3 of diphtheria, and 1 of smallpox.

Quarantine Station.—The health officer has reported favorably to the commissioners of the district on the proposed amendment to the appropriation bill providing for the purchase, erection and equipment of an isolation building. The estimates call for $10,000 for the site and $15,000 for the building and equipment.

Eight Hour Day for Nurses.—Mr. Mudd has introduced a bill in the House to regulate the hours of service and compensation of nurses and attendants at the Government Hospital for the Insane. It provides that quarters and rations shall be supplied, that eight hours shall constitute a day's work, and that 30 days' sick leave and 15 days' annual leave shall be granted.

To Prevent Spread of Disease.—Senator Hansbrough has introduced a bill for the further prevention of the spread of communicable disease in the District of Columbia. It provides for the immediate report to the health officer of all cases of measles, whooping cough, chicken-pox and epidemic cerebrospinal meningitis, and further provides for their supervision by the health department.

School Quarantine Regulations.—As the health officer has no legal authority to quarantine mild contagious diseases, the school board has adopted a resolution which provides that no children sick with measles or chicken-pox shall be admitted to the schools for a period less than three weeks from the onset of the disease. Those suffering from whooping cough shall not return to school for at least four weeks.

GEORGIA.

Erysipelas is a contagious disease, according to the Atlanta Board of Health, and hereafter those suffering from it will be isolated.

Counterfeiter Sentenced.—In Rome, January 31, sentence was passed on Dr. Russell D. Stallings, Clem, who was convicted about a year ago of counterfeiting.

Fined for Failure to Report.—Dr. Isaiah J. Griffith, Atlanta, was recently fined $25.75 for failure to report a suspicious case of illness which afterward developed into smallpox. By reason of his neglect, it is alleged by the city health officer that two deaths and at least four cases of smallpox have occurred.

Personal.—Drs. Henry M. Fullilove and A. C. Holliday, recently elected city physicians of Athens, have resigned because of the meager salary allowed them by the city council.——Dr. Thomas D. Longino, Atlanta, alderman and chairman of the council sanitary committee, has been elected president of the local board of health, vice Dr. William C. Jarnagin, term of service expired.——Dr. George Brown, Atlanta, has been made surgeon-general and Dr. J. Cheston King, assistant surgeon general, Georgia State Troops.——Dr. Charles J. Montgomery, Augusta, has been appointed a trustee of the Georgia State Sanitarium, Milledgeville, vice Dr. Eugene Foster, deceased. ——Dr. Theodore E. Oertel, Augusta, has been made temporary dean of the medical department, University of Georgia, Augusta, vice Dr. Eugene Foster, deceased.——Dr. Thomas D. Coleman, Augusta, has been designated to act as president of the local board of health until the vacancy caused by the death of Dr. Eugene Foster shall have been filled by election.——Dr. Harry Ainsworth, Thomasville, has been appointed traveling medical examiner for the relief department of the Atlantic Coast Line, with headquarters at Thomasville.

ILLINOIS.

Physician Afflicted.—Dr. Edward W. Paul, Forest City, is quarantined at his home on account of smallpox. It is said to be a mild case.

Smallpox Scare in Spring Valley.—On account of a case of smallpox brought into Spring Valley the Dominican Convent School in that city was closed and the convent placed in quarantine.

New Bills.—Bills have been introduced in the General Assembly, providing for the creation and establishment of the Illinois State Colony for Epilepties, and for the location, erection, organization and management of a state sanatorium for persons afflicted by tuberculosis.

Health Board Attorneys Paid by Fines.—In his annual report, the secretary of the State Board of Health announces that with the exception of $1,200 a year paid to W. A. Shaw as an investigator, all of the payments to special attorneys made by the board have come out of fines collected from violators of the law after prosecution by those attorneys. The practice of the board is to allow its special attorneys as fees all money collected as fines in consequence of prosecutions by them, they paying all costs. Thus the board's attorney in Chicago collected in fines from violators of the medical practice act, from June 1, 1901, to Jan. 10, 1903, $6,210.83. Of this amount he paid out in court costs, to investigators, agents to secure evidence, office rent, clerk hire, and other expenses, $3,997.28, leaving $2,213.55, which he was allowed to retain as fees.

Chicago.

New School for Nurses.—The Presbyterian Hospital is organizing a school for nurses, with a three years' course. Lectures will be given by members of the visiting staff of the hospital, and by the faculty of Rush Medical College.

Statement of Mortality.—In the week ended February 7 596 deaths were reported, an annual rate of 16.48 per 1,000, which compares unfavorably with that of the week previous, 16.20 per 1,000, and with that of the corresponding week of 1902, which was 15.18 per 1,000.

Colored Physician Wins Suit.—Dr. Anna B. Schultz was given a verdict of $2,037 for false imprisonment May 7, 1901, against several detectives of Pittsburg, Pa. They appealed to the United States Circuit Court for a new trial, and on February 2 this was refused and judgment was ordered for Dr. Schultz.

Physician Sued.—On February 5 a jury awarded an 18-year-old girl a verdict of $18,000 against Dr. George W. Webster, president of the State Board of Health. The plaintiff alleged that by reason of a mistaken diagnosis she suffered loss of her leg near the hip. Dr. Webster considers the case one of attempted blackmail, and will, if necessary, carry it to the highest court.

Smallpox to the Front.—The health department makes the following report for the week ended February 7:

Smallpox has been found during the week in all quarters of the city, and in most of the cases the source of the contagion could not be traced. Dr. Spalding, chief medical inspector, says: "The pest is attacking unvaccinated children under the school age of 6 years. Parents are careless about getting children vaccinated before they are compelled to do so when they present them at school. There are five children in the hospital under 6 years old."

Cold and Exposure Kill.—The health department announces:

Since January 1 there has been an increase of 36 per cent. in the deaths of infants and young children—under 5 years of age—and of more than 18 per cent. in the deaths of those beyond 60 years over the numbers in the corresponding thirty-eight days of last year. During this period in 1902 there were 3,058 deaths at all ages; this year the total deaths number 3,612—an increase of 18.1 per cent.

This chief increase of mortality among the aged is from pneumonia and from the chronic diseases—consumption, cancer, diseases of the heart and kidneys, and, to a lesser extent, from diseases of the nervous system.

KANSAS.

Bill to Govern Oculists.—A bill has been introduced in the senate providing for a state board of examiners in optometry.

Personal.—Dr. John J. Wood, Coffeyville, still holds the proud title conferred on him by Polk's Directory of being "probably the oldest physician in the United States, if not in the world," as he recently celebrated his one hundred and first birthday anniversary.

Many Medical Practice Bills.—Over a dozen bills regulating the practice of medicine have been introduced into the legislature. The principal one proposes to abolish the State Board of Medical Registration and require the State Board of Health to do the work of that body.

The State Board and Patent Medicines.—A bill was introduced in the senate, January 21, which will compel manufacturers of patent medicines to secure licenses from the State Board of Health before their medicines can be offered for sale or advertised in Kansas. The fee provided is $5. The bill also calls for an annual statement from the manufacturers showing the amount of medicine sold in the state, the statement to be accompanied by 2 per cent. of the gross receipts. Wagon peddlers will be required to pay a yearly license of $100.

Convictions and Arrests.—Dr. J. S. Hamilton, Coffeyville, has been convicted of the illegal practice of medicine.——In the Federal Court at Leavenworth, Kansas, Judge Hook recently fined J. W. Clements $25 for sending through the mails medicine known as a monthly regulator, the medicine and the directions accompanying it being held to be contrary to the statutes.——"Dr." J. C. Brownfield, formerly an itinerant medicine man, has been found guilty of forgery, at Eldorado, and sentenced to seven and one-half years in the state penitentiary.——Dr. Clement E. V. Sams, Haven, has been arrested on a charge of violating the quarantine law by failing to report a case of diphtheria in a family at that place.

MARYLAND.

Baltimore.

Contract Awarded.—The contract for the new surgical building for the Johns Hopkins Hospital has been awarded. It will be five stories high, of brick and stone, and will cost about $125,000.

Personal.—Dr. Smith Hollins McKim is making a voyage up the Nile.——Dr. Hector H. Goodwin sailed February 7 for a trip through Europe and the Mediterranean countries.——Dr. H. W. McComas, Oakland, has gone to Hot Springs, Ark., for a short sojourn.

Bequests.—Mrs. Margaret M. Smith, recently deceased, bequeathed $4,000 to the Church Home and Infirmary for the purpose of endowing a bed for an adult person, to be known as "The Charles Fisher Smith Bed," and also $1,000 to the Home for Incurables.

Medical College Sued.—Suit for $10,000 damages alleged to have been done the adjoining property by unwholesome smells and noxious matters issuing from the premises occupied by Baltimore University as dissecting rooms, has been brought against the owner of the property and the university.

Vital Statistics.—The death rate continues unusually high. There were 245 deaths during the week ended February 7, whereas for the corresponding week of 1902 the number was only 187. The annual rate per 1,000 was 23.22. A noticeable change in the proportion between the white death rate and that of the colored people was shown. Ordinarily the proportion is as 1 to 2 or 1 to 2½, but last week the proportion was as 21.67 to 31.70. The cause of this variation is not apparent. There were 40 deaths from pneumonia and only 28 from consumption. 234 cases of measles were reported.

The Wood Alcohol Blindness Suit.—The Boehm suit (see previous issues of THE JOURNAL) continues to excite deep interest. The experts for the defendants have contradicted the statements of the ophthalmologists, and testified that purified wood alcohol or Columbian spirits is no more poisonous than grain alcohol. Frederick T. Gordon, a pharmacist in the navy, testified to having taken one ounce twice a day. He also fed a cat a teaspoonful daily for over a month without harmful results. Dr. E. L. Whitney had taken 1½ ounces of Columbian spirits in three hours without bad effect. A special feature was the drinking in open court of 2 ounces of Columbian spirits by Mr. William E. Gilbert, one of the defendants. It was freely diluted with water, and no apparent ill effects were experienced. The counsel began arguing the case this week.

MICHIGAN.

Vaccination Train.—A special train containing vaccinators and vaccine has made the trip over the Grand Rapids and Indiana Railroad, leaving sore arms at every station. It is said that every employe of the road has been vaccinated.

Organization of Health Service.—The State Board of Health has been so successful in its endeavor to secure for every locality the appointment of a health officer, who shall be the executive officer of the board, that in the final report for 1902, returns were received from all but two villages and one township, out of nearly 1,600 townships, cities and villages in the state.

Physicians Win Suit.—One of the most tedious malpractice suits of recent years has just been decided in favor of the defendants in the Circuit Court of Macomb County. Drs. Henry G. Berry and Harry F. Taylor, Mt. Clemens, were called in 1901 to see a case of appendicitis. Dr. Angus McLean, Detroit, confirmed the diagnosis, and the appendix was removed. The patient died ten days later from uremic poisoning. Thereon suit was brought for malpractice, and damages of $10,000 claimed. As the defendants did not respond to offer of compromise, the case came to trial, and after a few minutes' deliberation the jury returned a verdict of "no cause."

In the Hands of the Law.—Dr. Roy W. Griswold, Bay City, convicted of complicity in the death of Agnes Eberstein by criminal operation, was sentenced, January 27, to imprisonment for two years in the state reformatory at Ionia.——W. I. J. Bruinsma, Olive Township, Ottawa County, has been arrested for practicing medicine without a state license. He was released on $500 bonds.——Henry M. Salisbury, Belding, has been arrested, charged with practicing medicine without a state license. ——Calfernia J. S. Smith, Grand Rapids, charged with having performed an unlawful operation on Bertha Van Norman, from the effects of which she died, was convicted and sentenced to imprisonment for seven years in the Detroit House of Correction.——D. C. Gee, Centerville, has been served notice by the State Board of Registration in Medicine to cease practicing medicine until he has complied with the law, and registered. ——P. Van Dystervelt, Little Muskegon, has been arraigned,

charged with practicing medicine without a license.——Dr. Wallace E. Newark, Charlotte, has been arrested, charged with causing the death of Mrs. W. H. Wirtz, by an illegal operation.

NEW YORK.

To Abolish Coroners.—A bill has been introduced into the legislature by Senator Elsberg for the abolition of the coroner's office of New York City and the substitution of a system similar to that of Massachusetts.

To Exempt Society Property.—A bill has been introduced into the legislature by Senator McCabe exempting from taxation property of medical societies in New York and Kings County to the amount of $150,000.

State Board of Charities.—The total number of beneficiaries in institutions subject to the inspection of this board was 60,804 on Oct. 1, 1902. There are 200 epileptics awaiting admission to the Craig Colony.

Typhoid Epidemic in Ithaca.—According to reports made to the board of health, Ithaca has a serious epidemic of typhoid, the total number of cases already reaching over 300. It is said that the epidemic has been traced to an infection of the city water supply.

A new quarantine hospital, costing $40,000, was recently opened at Rochester. The epidemic of smallpox is now practically over there being only 33 cases left in the old Hope Hospital. At one time there were more than 200 smallpox cases in Rochester. Many were cared for in the city election booths.

McKinley Memorial Hospital Incorporated.—An application for a charter for the McKinley Memorial Hospital for Diseases of the Digestive Organs was made to the State Board of Charities at Albany, January 10. The directors are Drs. Carl Beck, Ramon Guiteras, Reynold W. Wilcox, Mark I. Knapp and Mr. Edward Lauterbach of New York.

Stony Wold Sanatorium for Consumptives.—The board of directors of this corporation raised during the last week of January the sum of $18,000 for the work of the sanatorium. The organization has contributed $100,000 up to date toward the $200,000 building fund, and $6,000 has been given toward the endowment fund. The latest and largest gift, $20,000, was made by Mrs. Henry Siegel.

Opposed to Tenement Law Amendments.—At the January 27 meeting of the State Medical Society a resolution was adopted "deploring any weakening of the present tenement-house laws, and urgently requesting the legislature to permit no changes to be made that will in any way decrease the amount of light and air available for the people living in such houses, or in any way take a backward step in regard to their sanitary conditions."

Medical Examiners' Report.—The State Board of Medical Examiners was in session in Albany, January 28. The president, Dr. William Warren Potter, submitted the annual report, which shows that since the establishment of the board 7,034 candidates for license have been examined, of whom 5,528, or 78.5 per cent. have been successful, and 1,506, or 21.5 per cent., unsuccessful. The number of candidates for medical license has been decreasing since 1898. In that year the maximum, 869, was reached. In 1902 there were only 685. Dr. William W. Potter was elected president of the board for the ensuing year; Dr. Maurice J. Lewi, secretary, and Drs. George R. Fowler and Lewi were appointed a question committee.

Bubonic Plague and the Legislature.—A resolution has been introduced into the state legislature in anticipation of a probable outbreak of the bubonic plague in the east in the near future. The preamble rehearses what has happened in connection with the plague on the Pacific Coast and quotes from a recent conference at Washington of the representatives of state boards of health to the effect that it will be necessary for the Federal authorities to take cognizance of the spread of this malady, and that action on the Atlantic Coast will soon be imperative. The resolution itself is as follows:

Resolved, That the Commissioner of Health of the State of New York report to the assembly the part taken by him in the Washington conference, and the plans adopted or proposed to be adopted to prevent the introduction of the bubonic plague into this state.

New York City.

Vaccinators Dismissed.—The health commissioner has dismissed three physicians in the service of the health department in the Borough of the Bronx on the charge of falsifying reports of vaccination work. One physician reported that he had vaccinated 156 persons one week, when, it is said, the actual number vaccinated was two.

Arrests for Promiscuous Spitting.—Forty sanitary policemen were sent out in one day recently to arrest persons found violating the ordinance regarding expectorating in cars and other public places. The men made 39 arrests. It is announced that this crusade is to be kept up until the public show a proper respect for the law.

Summer Courses at Columbia.—An important extension of the work of the College of Physicians and Surgeons is the establishment of summer courses. This has long been under advisement, and will first be realized during the coming summer by the giving of practical courses in the various departments. Each course continues for from three to five weeks, and the work will be adapted to the needs of senior students and practitioners.

Rockefeller Laboratory for New York City.—Although no formal announcement has been made public, the fact has become known that Mr. Rockefeller has given a handsome sum for the erection of a fine laboratory, or probably a collection of laboratories for medical research. It is not denied that negotiations have practically been completed for the purchase of a large tract of land in the vicinity of East 80th Street. It is said that the ground alone will cost about three-quarters of a million dollars.

Mount Sinai Hospital.—At the annual meeting, January 25, President Isaac Wallach read the fiftieth annual report of the hospital. During the fiscal year ended Nov. 30, 1902, 34,879 cases had been treated, and there had been 6,287 applicants for admission and 3,032 patients admitted, this making a total of 75,569 patients since the founding of the hospital. The bequests to the hospital for the year amounted to $85,890, making a total of $1,366,000 so far contributed, and an additional $250,000 required to complete the building under construction at Lexington Avenue and Sixty-sixth Street. When completed the hospital will require about $225,000 per year for its support. At present it has a list of 3,705 members, an increase of 230 over the membership of a year ago.

Consumption in New York City.—According to the estimate of the board of health there are 30,000 persons in this city suffering from consumption, most of whom live in the tenement houses, and yet the city provides a hospital on Blackwell's Island accommodating 354, a pavilion for consumptives in connection with the Kings County Hospital, accommodating 65, and one at Bellevue Hospital which has at present only 10 beds for consumptives. In addition, about 200 patients are received at the Seton Hospital, a semi-private institution. Dr. Henry P. Loomis, therefore, very properly urges the building on Blackwell's Island, a site readily accessible from all the boroughs, and having a good supply of light and air, of a hospital sufficiently large to accommodate all consumptives who are very ill; this to be supplemented by a country pavilion annex for incipient cases.

Buffalo.

Typhoid in a Suburb.—The number of cases of typhoid fever in the steel plant district of West Seneca, a suburb of Buffalo, is increasing. There are at present 62 cases in the vicinity.

Antonius' Associate Fined.—Dr. Franklin Stuart Temple, an associate of "Antonius the healer," was fined $250 and $23 costs in the municipal court for failing to register with the department of health. Unfortunately Dr. Temple possesses a diploma from the Albany Medical College, and thus is protecting Antonius from criminal prosecution.

Consumptives Forsaken.—The board of visitors to the Buffalo State Hospital report that the consumptive patients are still in the forlorn corridors, forsaken and alone, except for necessary care, with none of the pleasant surroundings that mitigate the pain of mind consequent to a helpless condition of the body. Recommendations are made for a nurses' home and a residence for the superintendent.

Dr. Hall in Buffalo.—Dr. Winfield Scott Hall of the medical department of Northwestern University, Chicago, was the guest of honor at a banquet of the Alpha Omega Delta fraternity. He spoke on "Educational Principles in Medicine" and Dr. Matthew D. Mann, dean of the medical department of the University of Buffalo, also responded to a toast. Previous to the banquet Dr. Hall was entertained at a luncheon by Dr. Roswell Park and later a reception was given in his honor by Dr. Floyd S. Crigo.

OHIO.

Damage Suit Thrown Out.—The malpractice suit of John H. Minser against Dr. J. F. Baldwin, Columbus, was thrown

out of court by the presiding judge at the completion of the plaintiff's testimony, the court holding that the prosecution had failed to present a "scintilla of evidence" against the defendant.

Detail Contagious Diseases.—Dr. Probst, secretary of the State Board of Health, has issued the following list of contagious or infectious diseases: Smallpox, chicken-pox, diphtheria (membranous croup), scarlet fever, Asiatic cholera, bubonic plague, yellow fever, puerperal fever, erysipelas and typhoid fever.

Personal.—Dr. A. G. Appleby was recently burned by sulphuric acid, sustaining severe injuries.——Dr. George Bubb, Warren, has gone to Italy for a course of special study.——Dr. Morton W. Bland, Shelby, was seriously injured, December 9, by a fall from a train.——Dr. Francis E. Tibbitts, Geneva, major-surgeon, Fifth Infantry, O. N. G., has resigned.——Dr. George W. Crile, captain and assistant surgeon, Troop A, O. N. G., has resigned.——Dr. Nathaniel R. Coleman, after seven years of service, has resigned as president of the State Board of Medical Registration and Examination.——Dr. C. R. Justice, Poland, fell on the ice, January 20, dislocating his left elbow.

Cincinnati.

Personal.—Dr. Byron Stanton has been reappointed a member of the State Board of Health for a term of seven years.——Dr. Otis L. Cameron has resigned his position as city bacteriologist to accept the position of deputy coroner under Dr. Walter B. Weaver; Dr. William H. Crane has been appointed to succeed Dr. Cameron.

New Hospital.—Colored physicians of this city will soon erect a new hospital to be known as The Peter Fossett Memorial Hospital and Training School. Among those interested and who will probably form the staff are Drs. Norval C. Vaughan, Louis A. Cornish, Frank John, James C. Erwin, W. A. B. Kerr, and Duval Cooley.

Compulsory Vaccination.—There has been considerable opposition in Cincinnati to the stand recently taken by the local health department in regard to the compulsory vaccination of school children. The department has refused to accept the certificates of family physicians of repute and, as a result, over 3,000 children are absent from schools. The school principals, at a recent meeting, protested against this and appealed to the board of education, which advised the principals to accept the certificates of reputable physicians. The matter has been carried to the city corporation counsel, whose opinion is that the department has wide powers if it is thought that there is danger of a general epidemic. As it is hardly likely that the department is prepared to go so far, the board of education is conceded to have scored its point.

PENNSYLVANIA.

Suit Filed.—The widow of Dr. J. M. Broomall Wood has filed a libel to recover $75,000 damages for her husband's death. In the affidavit, his death is attributed to the neglect of the master and crew of the vessel in leaving the hatchway insecure down which Dr. Ward fell.

Joseph Huff.—It was erroneously announced, January 31, that Joseph Huff, deceased, was a graduate of the Western Pennsylvania Medical College in 1901. We are informed that he was a second-year student of that institution and that he died from exhaustion, consequent on cellulitis of the arm, while suffering from smallpox.

Examiners Reappointed.—Governor Pennypacker has made the following reappointments on the State Board of Medical Examiners: Regular—Drs. Henry Beates, Jr., Philadelphia; Hiram S. McConnell, New Brighton, and Robert W. Ramsey, Chambersburg. Homeopathic—Drs. John J. Detwiller, Easton; G. A. Mueller, Allegheny, and C. S. Middleton, Philadelphia. Eclectic—Drs. C. S. Johnstombaugh, West Bethlehem; L. P. O'Neal, Mechanicsburg, and C. M. Ewing, Tyrone.

Philadelphia.

Contagious Hospital Deeds Filed.—Deeds have been filed conveying to the city the Macalester farm of 58 acres in the Thirty-third ward, which will be used for the location of the Municipal Hospital. This insures the removal of the hospital for contagious diseases from its present site, a question long agitated.

Hospital Sued.—The Woman's Hospital is made defendant in a suit brought by Miss Vera Anderson to recover $5,000 damages alleged to have been sustained when a patient in the institution. She affirms that, while undergoing an operation for tumor, and while under an anesthetic, portions of skin, without her consent, were removed from her body and grafted on another patient. The latter procedure is made the ground for suit.

Hospital Project Fails.—The final meeting of an organization formed to build a private hospital, to be known as the McKinley Memorial Hospital, for the treatment of contagious diseases, was lately held. For about eight years an effort to collect funds for the building has been made, with rather poor success. The assets of the organization are $12,656. A considerable sum will be left after the settlement of the liabilities, and this sum will be kept and turned over to a similar organization that may be formed to carry on the work in the future.

UTAH.

Smallpox.—The prevalence of smallpox in the state is causing alarm. There has been a notable increase in the number of cases in Sanpete, Sevier, Salt Lake and Davis counties.

Want Unclaimed Bodies.—The Salt Lake County Medical Society has appointed a committee to request the legislature to pass a bill enabling the society to obtain unclaimed bodies to be used for scientific investigation.

Bound Over for Murder.—Dr. Edward S. Payne, Salt Lake City, charged with having caused the death of Miss Anna D. Hill, by a criminal operation, has been bound over to the District Court to stand trial on a charge of murder in the second degree, and in default of $7,000 bail has been remanded to the county jail.

Registration of Osteopaths.—By a bill introduced into the senate provision is made for an osteopathic board of registration and examination. The requirements for practice are the payment of a fee of $25, the presentation of a diploma of a reputable school of osteopathy, and the passing of an examination in such branches as the board may deem desirable.

Utah To Be Clean on One Day.—A bill has been introduced in the legislature setting apart the first Monday in October as a legal holiday, to be known as "Health Day." The act provides that:

> The owner, or in case of leased premises, the lessee in possession, of every occupied dwelling house, or living apartment and every hotel, restaurant, boarding house, church, school house, theater, rooming house, or dance hall, in active use, shall thoroughly disinfect the same on said "Health Day" with the disinfectant and in the manner provided by the State Board of Health.

Failure to do this is punishable by a fine of $50.

WISCONSIN.

New Hospital.—Charity Hospital has been incorporated at Stevens Point, without capital stock, by Drs. Carl von Neupert, and Frank A. Southwick and E. D. Glennen.

Medical Staff Dine.—The Board of Trustees of the Milwaukee Hospital for the Insane, Wauwatosa, and Dr. Moses J. White, superintendent of the institution, gave a dinner to the consulting staff of the hospital, January 30.

Medical Journal Incorporated.—The *Wisconsin Medical Journal* Company has been incorporated at Milwaukee, with a capital stock of $2,000, by Drs. Arthur J. Patek, Frank E. Walbridge, Arthur J. Burgess, and Solon Marks.

No Affiliation.—The regents of the University of Wisconsin have decided not to take action on the proposed affiliation with it of the Milwaukee College of Physicians and Surgeons. It was stated that the initial cost to the state of affiliation would be about $65,000.

Illegalities.—"Dr." A. W. Dude, Milwaukee, has been held to the Municipal Court on the charge of causing the death of Miss Alpha Leister by a criminal operation.——Suit has been brought against Drs. Harry A. Sifton and Leopold Schiller, Milwaukee, for $10,000 damages alleged to have been due to the unskilful setting of a broken leg.——Harry Spencer, Milwaukee, alias "Dr." Clark, convicted of securing a license to practice by false pretenses, plead guilty and has been sentenced to one year's imprisonment.——Louis Tauvars, a dentist of Marinette, has been arrested on the charge of practicing medicine without a license.

GENERAL.

Manila Cholera Gone.—Quarantine was raised at Manila, February 4, the government officials having declared the port free from cholera.

Rear Admiral Winslow Retired.—Medical Director George F. Winslow, after more than 40 years' service in the navy, was retired January 19 with the rank of rear admiral.

Congress Money to Fight Plague.—A bill has been introduced into Congress providing for a commission to investigate the conditions on the Pacific Coast and appropriating $50,000 to aid in stamping out the Mexican plague.

Army Hospital in Black Hills.—The Battle Mountain Sanitarium is to be established for sick and disabled soldiers at Hot Springs, S. D. Congress authorized the project, and a board selected the location because of the climate and springs.

Leaves Hawaiian Health Board.—Dr. H. C. Sloggett has resigned from the presidency of the Board of Health of the Territory of Hawaii, after efficient service. Dr. W. L. Moore is the probable successor, and Dr. W. H. Mays will be added to the board.

To Instruct Militia Surgeons.—The Secretary of War has a plan to give instruction to medical officers of the National Militia at the Army Medical School in Washington in the special subjects of camp diseases, wounds caused by weapons, camp hygiene and other military subjects.

Army and Navy Tuberculosis Hospital.—It is proposed to enlarge the Army Sanatorium at Fort Bayard, N. M., to make room for Navy patients. The enlargement would accommodate 100 patients and cost $100,000. The value of the Fort Bayard institution for the Army indicates its extension to include the Navy.

Foot and Mouth Epidemic Subsides.—Dr. Salmon of the Bureau of Animal Industry reports that the epidemic of foot and mouth disease is practically over. Not a single case of the disease has been reported outside New England, though a general epidemic was feared. He reports that about 3,000 animals so affected have been slaughtered in Massachusetts, Rhode Island, Vermont and New Hampshire, and that the government has paid the owners of the cattle a sum aggregating $100,000.

Army Contract Surgeons and Dentists.—The Secretary of War has decided that civilian physicians and dentists may be employed as contract surgeons and contract dental surgeons by the Surgeon-General of the Army. They will be entitled to transportation and fuel allowances of first lieutenant, and when on duty at a post or station where quarters are provided by the United States, they will be entitled to the quarters allowed by the regulations to an assistant surgeon with the rank of first lieutenant. They will not be entitled to commutation of quarters nor to the 10 per cent. increase of pay when serving beyond the territorial limits of the United States.

Pension for Colonel Walter Reed's Widow.—The House committee on pensions gave a hearing February 6 on the bill to provide a pension for Mrs. Emile Lawrence Reed, widow of the late Walter Reed, colonel United States Army Medical Corps, at the rate of $333.33 per month. The Senate has already passed a bill pensioning Mrs. Reed at the rate of $125 per month. Those who were invited to be present and address the House Committee were President Gilman and Prof. William Welsh of Johns Hopkins University, Prof. Alex. Graham Bell, Surgeon-General Robert O'Reily, U. S. A., Major J. R. Kean, medical department U. S. A., and Dr. H. L. E. Johnson, chairman of the Committee on National Legislation of the American Medical Association.

To Return the Remains of Yellow Fever Patients.—The Senate committee on the District of Columbia has reported favorably on the bill providing for the removal of the remains of two yellow fever patients from Santo Domingo to the District of Columbia for reinterment. The bill has received the favorable report of the district health officer. The report says that, as Mrs. Donaldson and her daughter died of yellow fever, the present law operates against the removal of their remains for burial in the District of Columbia, but, as investigations recently conducted by the late Major Walter Reed demonstrate that their removal can be accomplished without danger of infection, the committee reports favorably on the measure.

Mexico to Ask Plague Damages from U. S.—News from Mazatlan indicates better conditions. The supply of Yersin plague serum, long awaited, has arrived and is causing recoveries in many cases. The Mexican government investigation is reported to have shown that the disease was brought from San Francisco by a small steamer, the *Curazo*. That government will present a statement, it is announced, of the loss of life and extraordinary expense because of the infection, and will inquire what the U. S. Government wishes to do in the way of payment for these damages caused by San Francisco. The report that Guaymas was infected appears to be unconfirmed. Mexican officials say it will be difficult to eradicate the disease from Mazatlan because of the character of the poorer quarters of the city.

CANADA.

Hospital for Truro, Nova Scotia.—Various entertainments have recently been held in Truro for the purpose of raising funds for a new hospital, and a handsome amount has been realized.

Doctor Secures a Government Appointment.—Dr. Elliott of Wolseley, N. W. T., has been appointed commissioner of agriculture in the Haultain cabinet, in the place of Hon. A. L. Sifton, made chief justice of the territories.

Scarlet Fever Outbreak.—There is a pronounced outbreak of a malignant type of scarlet fever reported from several districts in Ontario, especially Leeds County and Peterboro. Many cases in Toronto this winter are also of a very severe form, several deaths resulting.

Ontario Asylums Full.—The report of the provincial inspector of asylums for Ontario for the past official year is now in the hands of the printers. It shows that practically every available bit of space for patients in the various asylums is taken up and provision for further room is urgently needed.

The Diet Dispensary of Montreal.—At the twenty-fourth annual meeting the secretary read the annual report which, owing to the change in date of the meeting, this year only embraces the work of nine and one-half months. During that time 10,842 orders were filled. The three nurses attached to the institution paid 4,073 visits. The financial report showed a balance to credit of the society of $606.35.

Canadian Alumni in New York.—At a meeting of the New York Graduates' Society of McGill University, Montreal, held January 30, the following officers were elected for the ensuing years. President, Dr. Wolfred Nelson; vice-presidents, Drs. James A. Meek and Hiram Vineberg. On the same day there was formed in the same city the University of Toronto Club. The graduates in Chicago and the west from McGill have also formed a society under the presidency of Dr. St. John.

Indians of the Dominion of Canada.—According to the annual report of the department of Indian affairs, the population of Indians on reserves throughout the dominion increased during the past year, through additions of Indians beyond treaty limits, by 7,518, bringing the total population up to 108,112. There was a somewhat heavy mortality among the children during the year, due largely to the prevalence of malignant measles. Apart from measles and smallpox, which hovered in the neighborhood of many of the northwest reserves during the year, the other disease most prevalent was tuberculosis. There were, during the year, 2,500 births and 2,349 deaths, or a net gain of 151, as against 239 for the preceding year.

Low Birth Rate in Ontario.—The registrar-general for Ontario, Dr. P. H. Bryce, again reports a decrease in the birth rate in Ontario for 1901. The births totaled 46,061 in 1901, as compared with 46,126 for the previous year. As for the birth rate in the cities, Ottawa alone, with 315 increase in population, showed a satisfactory increase in keeping with the increase of population. The report gives the number of marriages in 1901 as 18,035, an increase of 928 over the previous year. The number of deaths in 1901 was 29,608, a decrease of 114 from the preceding year. The deaths from tuberculosis numbered 3,243; in the previous year, 3,484, a decrease of 241. There were seven deaths from smallpox out of a total of 3,000 cases.

Medical Missionary Work in Labrador.—Dr. Wilfred T. Grenfell, superintendent of the Royal National Mission to Deep Sea Fishermen, Labrador, is now in Canada, and will shortly visit Chicago. The work, which is distinctly medical in its character, now extends to some 30,000 people, the object being to reach those isolated cases of sickness among the fishermen on the Newfoundland and Labrador coasts that otherwise would receive no medical or surgical treatment. Dr. Grenfell lectured in Toronto last week. His field covers 1,500 miles of coast. He is assisted by two physicians and two trained nurses. There are three hospitals located in the mission field, as well as two hospital ships to ply along the coast. During their first year, 1892, they treated 900 patients. Last year 2,774 were treated. The mission cost $20,000 last year, of which amount $2,000 was contributed by Canadians. The hospitals contain 24 endowed cots.

FOREIGN.

The plague in Natal, South Africa, is reported to be spreading seriously.

Typhoid Serum Search.—The typhoid problem in London has given a stimulus to the investigations of the *Bacillus typhosus* and the search for a serum.

The Ninth International Anti-Alcohol Congress will be held at Bremen, April 14-19. For particulars address the secretary, F. Hähnel, Dorandtstrasse 13, Bremen.

Trendelenburg Position as Remedy for Seasickness.—Marcel Baudouin, noticing the analogy between the effects of seasickness and of chloroform anesthesia, imagined that possibly the Trendelenburg position, which is sometimes able to avert vomiting in the latter, might prove equally effective in the former. Experiments on himself and others have convinced him of the correctness of his surmise, at least for certain individuals. In his own case, on a recent short voyage he was able to avoid all symptoms of seasickness by this means, but five minutes before reaching the dock he was obliged to rise to his feet when all the horrors of his usual seasickness befell him at once.

Appropriations for Medical Purposes in Germany.—The German government has appropriated $16,250 for experimental research on tuberculosis, with special reference to the relations between human and bovine tuberculosis, and protective inoculation of cattle. The statistics of the results of sanatorium treatment are also to be conducted with lavish care, and $3,750 has been appropriated for the 30,000 cards required. A sum of $2,500 has also been appropriated to pay physicians for repeated examinations of discharged sanatorium patients. A bacteriologic institute is also to be built near Berlin, at an expense of $19,000, and $12,500 has been appropriated for collection of statistics in regard to the morbidity and mortality of the various trades and professions. The greatest innovation, however, is the creation of three "flying typhoid stations," for which $37,500 has been appropriated. Each is to have a medical director and two assistants. They will be sent wherever typhoid fever is endemic, and stamp out the disease on the lines adopted for other infectious diseases. The total appropriations are thus nearly $100,000.

Post-Graduate Course in Medical Law.—A semi-official central committee in Prussia has been organizing free courses of post-graduate lectures in the various medical centers during the last year or so. They have proved extremely popular, and the committee now announce a course in medical law (Rechtskunde). The subject is to be divided into four branches: The physician before the law; medical responsibility; medical practice in its various social relations, and the organization of medical affairs. The first branch includes four lectures: Legislation in regard to the practice of medicine; public professional duties of the physician; the physician as a citizen before the law, and the judicial basis of medical practice from the economic standpoint. The subject of medical responsibility is disposed of in two lectures, one discussing the physician's councils, the other his professional acts. The third branch requires five lectures: The physician and medicine for the poor and the insane; in private insurance; in estimating the working capacity in regard to industrial insurance, and lastly, the physician and legislation in regard to drug stores. The Paris *Semaine Méd.* comments gloomily on the above as a striking proof of the way in which the "socialization" of the medical profession is progressing, while every step is a blow to the material interests of its members. Duties and responsibilities are being piled higher and higher on their shoulders, but their rights are never considered. The only legal privilege enjoyed by the physician is the right to sue a delinquent debtor. The editorial concludes with the remark that the profession must sooner or later resolve on some effective means of combating this incessant introduction of legislative or administrative measures, which are almost invariably detrimental to the material interests of the medical body. "But for our part," it adds, "and this avowal costs us much, we sincerely declare that we do not know of any effective measure."

LONDON LETTER.

The Social Influence of British Medicine in India.

Some time ago Dr. Takamine, the celebrated Japanese chemist, in an address delivered in Edinburgh, showed the important part played by medical science in initiating the Japanese renaissance—perhaps the most remarkable event in the history of the world. The wonderful practical capacity to assimilate western civilization of the Japanese was first brought into play by medicine. Their physicians quickly perceived the superiority of the practice of the Dutch medical men who settled in Japan in 1850-60 over the Chinese system which was in vogue, and proceeded to learn European languages and methods at a time when the government was hesitating to open foreign commercial relations. When these relations were established, the demand for Japanese with a knowledge of foreign languages was supplied by medical men and medical students. In similar manner and lesser degree British medicine has been, and probably will be, the most important influence in India in breaking down eastern prejudices and introducing western civilization. In a paper published in the *Asiatic Quarterly Review,* Surgeon General Beatson pays a well-deserved tribute to the Indian medical service, which he says has been associated with the foundation of the British Empire in India and has had a great influence in supporting it, in harmonizing differences, and in reconciling to British rule the multitude of races inhabiting India. Indian medical officers have been largely concerned in bringing to perfection the post and telegraph systems, the forest department, the management of gaols, and state sanitation. They have helped to introduce the study of English literature and science into the scheme of native education in India. They have established a system of medical education which has produced a well-educated class of native practitioners, who administer the hospitals and dispensaries provided everywhere by the government.

Proposed Compulsory Revaccination.

The president of the local government board has received a very influential deputation of the Imperial Vaccination League, which includes Sir W. Church, president of the Royal College of Physicians, Prof. Clifford Allbutt, the chief rabbi, Dr. Patrick Manson and Dr. McVail. Dr. McVail pointed out that the evidence in favor of vaccination applied equally in favor of revaccination. The league requested that when a child was approaching the age of 12 the parents should receive notice requiring revaccination, but it did not propose to interfere with the so-called "conscientious objector." Mr. Long, the president of the board, entirely sympathized with the object of the deputation and promised to bring the matter before his colleagues in the government. Any attempt to reform the law would meet with violent opposition from the anti-vaccinationists, but he thought that if the principle of allowing exemption to the "conscientious objector" were preserved, no opposition would come from reasonable people.

X-Rays Cure Xeroderma Pigmentosum.

At the Edinburgh Medico-Chir. Society Dr. Allan Jameson showed a case of xeroderma pigmentosum which had been treated by the *x*-rays. The patient was a little girl, the youngest of two children, who had suffered from the disease. At the age of 12 months she began to develop freckles at the side of the nose. Later telangiectasis and whitish spots began to develop on the face. The disease had extended to the hands and wrists. When seen on October 1 there were an epitheliomatous growth on the tip of the nose of the size of a sixpence and numerous warty growths on the face. Thirty-four exposures to the *x*-rays, each of 5 minutes for the face and 13 minutes for the right hand were given. The growth on the nose and all the warts on the face disappeared. An *x*-ray dermatitis was produced. The nose is now whiter than the rest of the face and there is marked improvement of the right as compared with the left hand. This case shows the difference between the action of the *x*-rays and the ordinary actinic rays of the spectrum, for the latter tend to increase pigmentation of the skin.

The London Hospital.

In an appeal for help addressed to the *Times,* the chairman of the London Hospital, the largest hospital in the metropolis, brings forward some interesting statistics of the institution. Last year there were 13,160 in-patients and 162,147 out-patients. To these people 2,500,000 pills and about 3 tons of cough lozenges were dispensed. In dressings 92 miles of lint, 476 miles of bandages, 6 tons of cotton wool and 9 miles of plaster were used. Every day half a ton of ice and 400 siphons of soda water are consumed. It costs $425,000 a year to maintain the hospital. Great improvements have recently been made. An isolation block has been built, at a cost of $160,000, 5 of the finest operating theaters in the world at a cost of $65,000, a pathologic department at a cost of $100,000, and a new out-patient department at a cost of $350,000, which will be opened by the king.

Correspondence.

A Criticism of Pneumonia Mortality Statistics.

Denver, Jan. 28, 1903.

To the Editor:—Your editorial of January 24, on Dr. Reynolds' announcement of the increased mortality from pneumonia (Bulletin of Chicago's Health Department, January 17), being under discussion, permit me to add a word. I would not seem to detract from the just conclusion that we are evolving a better resistance to and curative management of tuberculosis, as shown by the lessening mortality from consumption during the past forty years. However, it is but right we should recognize any coincident facts in the history of these two diseases, consumption and pneumonia, which might explain the remarkable changes in their reported mortality results.

You mention influenza infection as a contributing cause of this increased pneumonia mortality, and we all know that it not only enters into the etiology, but also gravely influences the prognosis of pneumonia. In this discussion it is unfortunate, yet perhaps not to be avoided, that acute lobar and catarrhal pneumonias are classified with the chronic and fibroid variety under the name of pneumonia. But the fact of the prolongation of life through the arrest of tuberculosis should be recognized as opening up a larger field for the ravages of acute pneumonia, because this inflammatory infection is a frequent *method of dying* for the tuberculous. This is important for, so far as these two diseases are concerned, every death ascribed to pneumonia which might otherwise, in justice to the predisposing cause, tuberculosis, be classified as tuberculosis, is "robbing Peter to pay Paul," and doubles the addition to or subtraction from a given percentage, as the case may be.

That there have been influences at work during the past twenty to forty years contributing to such an unjust classification of these consumptive-pneumonia statistics is a fact to which I wish to call attention.

First, the growing fear of the contagiousness of tuberculosis, the prevalent "phthisiophobia" which, it is to be hoped, has now about reached its climax, infecting the minds of physicians as well as of the laity; this leads to a tendency to call the chronic disease anything rather than tuberculosis. In this day and generation a person is not going to brag much of having tubercle bacilli in his sputum, especially if he is under the unenviable necessity of hunting a boarding house in a new town. The greater danger of infecting one's self than of infecting another goes unrecognized; and it is much nicer to die under the egis of pneumonia, either acute or chronic, "heart failure," or nervous exhaustion than the dreaded tuberculosis!

Second, and very important, it seems to me—almost everybody has his or her life insured. The insurance companies, naturally prejudiced against tuberculosis, are constantly more and more vigorously "hedging" against losses by that route. From the standpoint of the insured and his beneficiary, a dyscrasia or weakness which was the commencement of a finally fatal tuberculosis must be covered up by some cause which is immediate and unobjectionable—more respectable, so to speak. The wish is often "father to the thought," and the death certificate may perhaps be influenced by this sophistry. If there is any excuse for it, pneumonia is given as the cause of death. Again, the doctor who has unfortunately made a mistaken diagnosis of malarial fever instead of concealed acute tuberculosis which really exists, is he going to change his opinion when he writes the death certificate? Perhaps this is another case of "where ignorance is bliss 'tis folly to be wise."

Anyway, it often happens, I believe, that the *immediate* cause of pneumonia takes the place of the *remote* cause, tuberculosis, in the death certificate. Take as an example a young man I have lately seen. He says he was insured a year ago in a respectable company. He did not particularly care for the insurance, but the agent was a friend of his who was sure he would be accepted. So he was, but how wisely is shrouded in doubt when his history and present condition, in the third stage of pulmonary tuberculosis, are taken into account. Now, supposing he were at home in the environment of this mistaken estimate of his life possibility, supposing he should there have any form of pneumonia, or supposing he had had it at any time in the last half year, and, with not more than one chance in fifty of living, had died, would the pneumonia or the tuberculosis have gotten the credit of the death? From my knowledge of other cases of the kind, I should say the chances are vastly in favor of the pneumonia. Yet in private practice how seldom death occurs in middle life from uncomplicated pneumonia.

So much depends on the *soil* in which the infectious pneumonia *seed* is planted that statistics of the relative prevalence of pneumonia and tuberculosis are bound to be affected, notwithstanding we endorse the explanation of Chicago's Health Commissioner for the greater prevalence of pneumonia in winter, namely, the close housing of people in unventilated homes.

The suspicion is strong in the mind of the writer that much of the difference in mortality statistics of consumption and pneumonia during the past twenty to forty years is to be accounted for by the results of increasing prejudice, however unreasonable it may be, against consumption.

Charles Denison.

Connell Suture Not Cause of Death.

Leadville, Colo., Jan. 31, 1903.

To the Editor:—On page 91 of the December issue of the *American Journal of Surgery and Gynecology* I notice an item entitled "Death from the Connell Suture." A perusal of this item reminds one of the definition that appeared some time ago in a small school dictionary, where the word "crab" was defined as "a red fish that crawls backward." Now, to the superficial observer, this definition was eminently satisfactory; but to the inquiring mind—one that was after the facts in the case—it was found to be all right, too, except that a crab is not red, nor is it a fish, nor does it crawl backward.

So, too, with the item referred to, the superficial observer is satisfied. It is enough for him to read that death and the fatal hemorrhage were caused by the "Connell suture," and that had a "Czerny-Lembert suture been employed, this fatal termination might have been prevented." One after the facts, however, would find that the Connell suture was not employed, nor did the method that was employed cause the fatal hemorrhage, nor would a Czerny-Lembert have prevented the fatal result.

The feature most enthusiastically recommended in the Connell suture is the placing of all the knots in the lumen of the bowel, after penetrating the entire intestinal wall. This was not done in the fatal case of Dr. Tait, in which the gastroenterostomy was finished with two Lembert sutures, including but a portion of the walls and knotted on the serosa. The method that Dr. Tait did employ did not cause the hemorrhage, but it was the direct result of the use of the interrupted suture. When the abdomen and stomach were opened a second time, the hemorrhage was immediately stopped by the insertion of a whip stitch, continuous, penetrating all coats and knotted in the lumen.

Kocher has already, and in a very forcible manner, called attention to the importance of the continuous suture in gastric surgery, in the following terms: "The continuous suture so warmly advocated by Rydygier and Lauenstein appears to us to be absolutely essential to success," and farther on in the same paragraph, "moreover, it appears very important to carry the continuous suture through the entire thickness of both gastric and intestinal walls, as it is only by this means that reactionary hemorrhage, which has been the cause of, at any rate, a certain number of fatal cases, can be prevented with certainty." *A priori*, it would appear that the Lembert suture, penetrating the walls of the stomach and bowel a part of the way only, would have no advantages, as a hemostatic, over the stitch that penetrates all the coats.

By the inquirer after the facts it will be found that the patient died from hemorrhage, following gastroenterostomy, and that death from this cause has been reported, and steps to prevent this fatal result have been recommended long before the Connell suture had been devised.

F. GREGORY CONNELL.

The Medical Library Journal.

To the Editor:—In the issue for January 31 of THE JOURNAL there is an editorial on a *Medical Library Journal*, as you say, edited by "Doctors Albert Tracy Huntington and John Smart Browne." May I ask you to correct this? Neither of these editors is a doctor. If you will take the pains to read the index heading in the first number of this monstrosity of a journal once more you will convince yourself that these editors furnish conclusive evidence that they are no men of learning, no doctors. It is to be hoped that nobody will quote titles of books from the list given in this *Library Journal*, because many of these titles are misspelled. A. ROSE.

Marriages.

B. S. ADAMS, M.D., Hibbing, Minn., to Miss Vida Brugger of Minneapolis, January 29.

SIMON CUTHBERT LEVY, M.D., to Miss Lillie Silber, both of Plaquemine, La., January 28.

SAMUEL LOWRY BEARD, M.D., to Miss Jessie McClure, both of Shelbyville, Ky., February 11.

WILLIAM E. JEWETT, JR., M.D., to Mrs. Lulu Bean-Spence, both of Adrian, Mich., January 28.

ALBERT M. CLINKSCALES, M.D., Vinita, I. T., to Mrs. Lucie Matkin of Winsboro, Texas, January 20.

WILLIAM HAYDEN ROCKWELL, JR., M.D., to Miss Mary Jane Watson Haight, both of New York City, February 14.

I. HAMILTON GOSS, M.D., Athens, Ga., to Miss Virginia Cary Anderson of Clarksville, Tenn., at New Orleans, January 27.

HAROLD D. CORBUSIER, M.D., acting assistant surgeon, U. S. A., to Miss Louise Shepherd of Battle Creek, Mich., February 4.

Deaths.

John Morris, M.D. Bellevue Hospital Medical College, New York, 1868, of Baltimore, a member of the legislature, 1852-56; member of city school board, 1856-57; postmaster of Baltimore, 1857-61; member of city council, 1867; president of Pathological Society, 1868 and 1872; president of Maryland Inebriate Asylum, 1875-77; president of Baltimore Medical and Surgical Society, 1874-75; president of Baltimore Medical Association, 1879; vice-president of American Medical Association, 1879; vice-president of American Chirurgical Faculty of Maryland, 1888-89; president of Pennsylvania and Maryland Medical Society; president of the Maryland State Board of Health, and up to the time of his death president of the Lunacy Commission of Maryland, died at City Hospital, Baltimore, January 29, from nephritis, aged 79, after an illness of eight months. During the epidemic of yellow fever in Norfolk and Portsmouth, Va., in 1855-56 he volunteered his services as physician to the stricken cities, and there contracted the disease, recovering only after a tedious illness. He was given a gold medal by the citizens of Norfolk for his services on this occasion.

James M. Ridge, M.D. University of Pennsylvania, Philadelphia, 1852, of Camden, N. J., a member of the American Medical Association, Bucks County (Pa.) Medical Society, Pathological Society of Philadelphia, Camden County Medical Society, and New Jersey State Medical Society; a member of the Camden Board of Education for sixteen years, and for a long term one of the New Jersey State Board of Health, died at his home in Camden, January 30, after an illness of more than a year, from Bright's disease, aged 76.

J. M. Broomall Ward, M.D. Jefferson Medical College, Philadelphia, 1891, of Chester, Pa., quarantine physician at Marcus Hook Station, was killed, January 21, by falling through the hatchway of the Danish steamer *Euxinia*, which he had boarded for inspection. Dr. Ward was major and surgeon of the Sixth Regiment of the National Guard of Pennsylvania, and was a member of many medical organizations.

Ira L. Welch, M.D. University of Wooster, Cleveland, 1879, some-time president of the Fort Dodge Medical Society and of the Boone Valley Medical Society, a member of the Iowa State Medical Society, county treasurer for four years, and a member of the state legislature, died at his home in Humboldt, Iowa, January 25, from paralysis, after an illness of three months, aged 74.

William Gibson, M.D. Pennsylvania Medical College, Philadelphia, 1853, a member of the American Medical Association, and one of the oldest physicians of Alexandria, Va., died at his home in that city, January 28, aged 73. At a meeting of the Alexandria Medical Society, held January 29, resolutions of respect to the memory of Dr. Gibson were adopted.

John Murphy, M.D. University of Edinburgh, Scotland, 1840, for nearly 50 years a practitioner of Peoria, Ill., died at his home in that city, January 21, from debilities consequent on old age, after an illness of several weeks, aged 86. He retired from active practice in 1897.

Pembroke M. Womble, M.D. Jefferson Medical College, Philadelphia, 1847, died at his home in Baltimore, January 30, aged 75. He was associated in practice with the late Dr. J. R. W. Dunbar, and retired from practice in 1884 on account of heart disease.

Walter B. Wine, M.D. University of Maryland School of Medicine, Baltimore, 1893, was found dead in his office in Dupuyer, Mont., January 7, and the coroner's jury found that he had met his death by blows delivered from behind his back.

James Mercer Garnett McGuire, M.D. University of Pennsylvania, Philadelphia, 1855, who served as major and surgeon in the Confederate Army, died suddenly at his home in Berryville, Va., January 24, from heart disease, aged 70.

Augusta B. Engstedt, M.D. John A. Creighton Medical College, Omaha, 1899, of Oakland, Neb., died at St. Joseph's Hospital, Omaha, January 26, after an operation for cancer, aged 29.

Roswell P. Chambers, M.D. Columbus (Ohio) Medical College, 1877, of Portland, Ore., died while undergoing an operation at the Good Samaritan Hospital, Portland, recently, aged 49.

James G. Leffingwell, M.D. University of Michigan, Ann Arbor, 1870, of Pittsburg, Pa., died at Wilkinsburg, Pa., January 29, after an illness of two weeks, from pneumonia, aged 57.

Hawkins Stone, M.D. University of Virginia, Charlottesville, 1837, who had practiced more than 60 years in Garrisonville, Va., died at his home near that place, January 20, aged 87.

Irwin L. Benner, M.D. University of Pennsylvania, Philadelphia, 1893, of Sellersville, Pa., died, January 24, at the home of his parents in Iron Hill., Pa., from typhoid fever, aged 30.

James E. Walters, M.D. University of Michigan, Ann Arbor, 1884, died from pneumonia, after an illness of three days, at his home in San Miguel, Cal., Dec. 26, 1902, aged 40.

Hilbert B. Tingley, M.D. Baltimore University School of Medicine, 1889, of Oceanus, Rockaway Beach, was instantly killed, January 14, while attempting to board a train.

Herman Mynter, M.D. University of Copenhagen, Denmark, 1871, died at his home in Buffalo, N. Y., February 9. A more extended notice will appear in the next issue.

Isaac George Reed, M.D. University of Pennsylvania, Philadelphia, died, January 24, in the Manhattan State Hospital for the Insane, Ward's Island, N. Y., aged 67.

John Gabriel Seabrook, M.D. University of Pennsylvania, Philadelphia, 1844, died at his home in Columbia, S. C., January 20, after a long period of invalidism, aged 81.

I. K. Scott, M.D. Starling Medical College, Columbus, Ohio, 1872, died from consumption, January 10, at his home in Larue, Ohio, after an illness of a year, aged 59.

Samuel E. Burchfield, M.D. University of Michigan Homeopathic Medical College, Ann Arbor, 1881, died from sepsis at his home in Latrobe, Pa., January 21, aged 48.

Wellington C. Burke, M.D. University Medical College, Kansas City, 1892, died at his home in Los Angeles, Cal., January 15, after an illness of five weeks, aged 36.

John C. Hackett, M.D. Jefferson Medical College, Philadelphia, 1883, died at his home in Millington, Md., January 21, from paralysis, after a long illness, aged 45.

John C. Tribbett, M.D. Miami Medical College, Cincinnati, 1873, died at his home in Montezuma, Iowa, January 20, from pneumonia, after a short illness, aged 56.

William L. Martin, M.D. Jefferson Medical College, Philadelphia, 1852, died at his home in Rancocas, N. J., January 27, from pneumonia, after a short illness.

Charles H. Haessler, M.D. College of Physicians and Surgeons, New York, 1853, died at his home in Pottsville, Pa., January 22, from diabetes, aged 73.

Stephen C. Johnson, M.D. Albany Medical College, 1849, died at his home in Luzerne, N. Y., January 27, from la grippe, complicated with cystitis, aged 77.

Alexander Scott, M.D. Detroit Medical College, 1871, three times health officer of Forest, Ont., died suddenly at his office in that place, January 20, aged 62.

John Lord, M.D. Medical School of Maine, Bowdoin College, Brunswick, 1866, died at his home in Biddeford, Maine, from shock, January 21, aged 59.

James Elliott Sweet, M.D. University of Michigan, Ann Arbor, died at his home in Hartford, Mich., January 12, from heart disease, aged 82.

Theodore F. Stair, M.D. Chicago Medical College, 1871, died suddenly from heart disease at his office in Evansville, Wis., January 17, aged 59.

Gerald D. Fitzgerald, M.D. Queen's University, Kingston, Ont., 1893, of Amherst, Nova Scotia, died, January 10, from apoplexy, aged 31.

Elizabeth L. McMahon, M.D. Homeopathic Medical College of Missouri, St. Louis, 1875, died at her home in Marion, Ohio, January 17.

George Blakey Proctor, M.D. University of Nashville, Tenn., 1895, died at his home in Milton, Fla., January 16, from typhoid fever.

John W. Smith, M.D. Kentucky School of Medicine, Louisville, 1853, died at his home in Gosport, Ind., January 11, aged 73.

Albert Dunlap, M.D. University of Maryland, Baltimore, 1864, died at his home in Creston, Iowa, January 13, aged 63.

James Morton McKim, M.D. St. Louis Medical College, 1858, died at his home in Newark, Mo., January 22, aged 76.

John V. Epler, M.D. Pennsylvania Medical College, Philadelphia, 1858, died at Reading, Pa., January 20, aged 65.

George D. Slocum, M.D. University of Buffalo, 1861, died recently at his home in Marine City, Mich., aged 62.

E. McClain, M.D., of Lawrenceburg, Tenn., died, January 14, from pneumonia, after an illness of one week.

J. B. Holcomb, M.D. Albany, 1885, of Newport, N. Y., died at the county house near Middleville, recently.

A. E. Bentley, M.D., died at his home in Hopkinsville, Ky., January 19, from paresis, aged 65.

James H. M. Knox, Jr., M.D., died at his home in Baltimore, January 21.

Book Notice.

How to Succeed in the Practice of Medicine. By Joseph McDowell Mathews, M.D., LL.D., President of American Medical Association. 1898-9. Cloth. Pp. 215. Price, $2.00. Louisville: John P. Morton & Co. 1902.

However much and justly we may exalt medical teaching of to-day when we recall what it was twenty, even ten, years ago, the candid must admit that the student still leaves college, in some respects, poorly equipped for the successful practice of medicine. All can not serve as resident physicians in a large hospital where every variety of disease will be shown, explained and successfully treated. All can not have the opportunity to observe and associate with leaders, perhaps masters, in the profession and study them as well as their cases, and in this way understand and appreciate why they have been successful socially, professionally and financially. All should have what few, if any, schools give their classes, a more practical insight into the business side of our profession—for are we not business as well as scientific men and women? True it is that most schools give a so-called course on ethics and medical jurisprudence which is so superficial and incomplete as to be of very little value.

This course, which is now technically compulsory, could easily be so amplified as to really teach ethics in such a way as to enable any beginner in the noblest of professions to so conduct him or herself at the outset as to enlist the sympathy and the support of older practitioners so that they would extend a helping hand to ambitious, worthy, and modest novitiates instead of attempting to crush them under the iron heel of disparagement, social ostracism, and contumely.

Faulty as may sometimes be the reception given new comers by those already established, who seem to think that the place belongs to them and that it is rank impertinence in other Richmonds to enter the field, it has ever been my observation that the greater fault was on the other side. It is hardly fair to expect the members of a profession to enthuse over and take into their arms a newcomer who calmly announces on the street corners, the court-house steps and at prayer meeting that he has been asked to settle there "because the town actually needs a good, moral, and sober doctor." Everyone has known of such instances; most of us dozens of them. It is indeed the rock on which the hopes of most young men are dashed to pieces, and they make the mistake once, twice, perhaps three times, before it suddenly dawns on them that it is about time to find an abiding place, and that "A rolling stone gathers little moss." The next place they move to they learn that it is better to say respectful and decorous things of the leading practitioners instead of hinting that they are "back numbers," "drink too much," "give too strong medicine" and all such stuff that is never taken seriously by listeners, but instead rightly estimated as jealousy. It is even much better after waiting a reasonable time to waive all formality and make the first call, assuming that the intentions of his competitors are the best, and that a want of opportunity, not inclination, has prevented them from calling first. They are far more likely to throw a case to such a man than to one who speaks harshly of them because of an unintentional slight. After the first meeting comes the first consultation. How necessary is it for the young man to bear himself with becoming modesty, dignity and yet self-confidence, for by his behavior now will he be judged by the community hereafter.

This little book of Professor Mathews is verily a "Multum in Parvo." No young man entering the profession can afford to miss the good advice to be found in it and given withal in such an interesting way. It is not only full of good advice, but teems with wit, eloquence and good cheer. Those of us who have known the author for many years; who have basked in his sunshine and been the recipients of his kindness; ever receiving just a little more courtesy than the occasion or our merits led us to expect, will not wonder at the great success of Professor Mathews' life. To those who have not known him intimately this little book is the key. I know that he acted and preached to the students of the Kentucky School of Medicine the gospel he now writes to the students of other schools and the general profession.

He was the most considerate and delightful of colleagues; a charming and versatile lecturer; and his "heart-to-heart talks with the boys," of which this book is practically a compilation, were thoroughly enjoyed by all, and I doubt not, have been the guiding star in the lives of many of his successful students. I wish that it were possible, in the space allotted, to refer to the different chapters and point out the merits of each. Suffice it to say that all contain valuable suggestions and advice—from the first, which largely deals with the questions of preliminary education, habits, morals, etc., of the physician, to the last, a beautifully pathetic one on lights and shadows.

The chapters on "marriage," "specialties in medicine" and "medical societies" are particularly good. Concerning "specialties," the author gives the best possible advice, and holds to views that will be heartily endorsed by practically all save those he well denominates pseudo-specialists.

The chapter on medical societies is short but much to the point. The advice here given, if followed, will make anyone a useful member of his society, and, if he has natural ability, a brilliant one.

Perhaps as interesting a chapter as any is the one on "Art in Medicine." From it the young physician will glean much of real value to him, both as a professional and business man. In no other part of this book is the rare common sense and

acute observation of the author more in evidence. It emphasizes what every observant practitioner knows—that a knowledge of drugs is oftentimes distinctly of less value in the treatment of disease than diet, exercise, vocation, climate, interesting books and beautiful flowers. Certainly the practitioner who is full of sympathy and humanity for his fellow man; who is eclectic in its broadest sense; who studies patients and anxious relatives as well as disease, will, other things being equal, meet with the fullest measure of success. Cheerfulness of mien and a proper knowledge of how to enter and leave a sick room, be it one of anguish or hope, constitute, perhaps, the most valued asset of the family doctor.

No one is more competent than the gifted author to write such a book. His varied experience, first, as a general practitioner in the country; later, as a successful specialist in a city; his twenty-five years' experience as a teacher; his large acquaintance with the profession of America and Europe, which has brought him the highest honors within the gift of his confrères, municipal, state, and National, all eminently fit him to send this message of sunshine and usefulness to the younger and struggling members of our guild.

The knowledge that he has succeeded in lightening the burden of others, will, I am sure, be the author's greatest reward for having written this delightful little volume.

WM. L. RODMAN.

1626 Spruce Street, Philadelphia.

Queries and Minor Notes.

ANONYMOUS COMMUNICATIONS will not be noticed. Queries for this column must be accompanied by the writer's name and address, but the request of the writer not to publish his name will be faithfully observed.

WANTS AUTOMOBILE INFORMATION.

BOULDER, COLO., Feb. 4, 1903.

To the Editor:—In this the "horseless age," I am sure that many physicians are seriously contemplating the purchase of automobiles, yet have some misgiving as to their being at this time on a basis practical enough to entirely displace the horse. May we not hear through your columns from some members of the profession who have had experience with them? I am sure such information will be very much appreciated by a large number of your readers.

OSCAR M. GILBERT.

SYRINGE STERILIZATION.

ST. LOUIS, Feb. 2, 1903.

To the Editor:—Kindly state in your Queries and Minor Notes Column the best manner of sterilizing a new syringe (glass barrel).

J. R. CLEMENS.

ANS.—The syringe should be taken apart and boiled for about fifteen minutes in a 1 per cent. solution of sodium bicarbonate. If the plunger is of rubber, this will not harm it, if it is kept away from the sides and bottom of the vessel in which it is boiled. If the plunger is of leather it is hard to say how it can be sterilized without injury.

MEDICAL PRACTICE QUERIES.

CHICAGO, Feb. 9, 1903.

To the Editor:—Please give me the addresses of the secretaries of the boards of medical examiners in Iowa and Minnesota.

C. C. SMITH.

ANS.—Minnesota, Dr. C. J. Ringnell, Minneapolis; Iowa, Dr. J. F. Kennedy, Des Moines.

WASHINGTON, D. C., Feb. 8, 1903.

To the Editor:—Will you kindly inform me of the requirements for practice of medicine in the state of Oregon? To whom can I write for information? M. FLORES.

ANS.—An examination is required. Write to the secretary of the State Board of Medical Examiners, Dr. Byron E. Miller, Portland.

THE PHYSICIAN AND THE PHARMACOPEIA—METHOD OF REDUCING STRENGTH OF SOLUTIONS.

U. S. MILITARY HOSPITAL, FT. SLOCUM,
NEW ROCHELLE, N. Y., Feb. 5, 1903.

To the Editor:—Referring to the letter of Dr. Hughlett Hardcastle communicating his discovery of a formula for the reduction of percentage solutions, published on page 257 of THE JOURNAL of January 24, permit me to invite the attention of the Doctor and yourself to foot note on page 131 of the eighteenth edition of the United States Dispensatory, in which the formula and several others of equal value are published. This edition is now and has been for the past five years the official standard in its line.

Very respectfully, ARTHUR NEVILLE,
Hospital Steward, U. S. Army.

HYDROGEN PEROXID—ABSCESS DRESSING—LUDWIG'S ANGINA.

NEW YORK, Feb. 5, 1903.

To the Editor:—Kindly inform me as to the exact region and anatomic structures involved in angina Ludovici; 2, also the present status of opinion as to the use of hydrogen peroxid in the irrigation of abscess-cavities; and 3, the kind of dressing that would best suit an abscess that has been opened and the walls of, and tissues surrounding, which are indurated and inflamed? A. M. S.

ANS.—1. Ludwig's angina is an acute phlegmon of the connective tissue occupying the space from the symphysis menti to the hyoid bone, usually but not always unilateral, though not sharply defined and due most commonly to an infection with a streptococcus or staphylococcus. 2. The use of hydrogen dioxid in the irrigation of abscess cavities is not nearly so general as it was a few years ago, though it has advantages in special cases. Do not use it in wounds or cavities without free exit for the gas formed. 3. As a general proposition, a not, moist, antiseptic dressing.

LEMON JUICE PROPHYLAXIS AGAINST TYPHOID.

ROGERS PARK, CHICAGO, Feb. 6, 1903.

To the Editor:—At the present time, when so much notoriety has been given to the use of lemon juice to kill typhoid bacilli, I would like to state it is *not* a new fact, as appears to some. Many years ago I was warned to use lemon juice when traveling, as was the custom of my father, the late Dr. John Latham, of Lancashire, Eng. He made a practice of doing so and urging patients to do the same. Since teaching in universities I seldom failed to give the same suggestion to students, especially those from out-of-town districts, until they became used to the water supply. So many people have used the lemon with water to get rid of the earthy or brackish taste in mountain and country districts, and especially on shipboard in the tropics, that it was always thought it was for safety. Another use is the drinking and gargling of throats or swabbing by the grandmother or parents in children suffering from diphtheria, for it is well known to kill the bacilli very quickly—especially when used pure. Its use may be compared to the common practice of gargling with vinegar, or the use of tobacco ash and vinegar for ringworm, and such old household remedies, whose scientific value has not been worked out. It is to be hoped that lemon juice may be worth the position given it for it is certainly an easier, simpler and more palatable remedy for a common and preventable disease. Again, sailors are apt to regard lemons as a cure for jaundice, liver troubles and their allies, as it is supposed to act on the bile both to aid its antiseptic and intestinal effects. Few sailors will go to the tropics without lemons or lemon juice and as one who sails the Brazil said, "It's better than your pills except quinin for the chills," and here again they remember it aids in solubility and flavor. V. A. LATHAM.

Association News.

New Members.

List of new members for January, 1903:

ALABAMA.

Anderson, E. C., Anniston.
Greene, A. A., Anniston.
Chilton, D. H., Corona.

Societies.

Saline County (Neb.) Medical Society.—This society was organized at Crete, January 30.

Decatur (Ill.) Medical Society.—The second annual banquet was held at the Decatur Hotel, January 23. Covers were laid for forty-six.

Robertson County (Tenn.) Medical Society.—This society was organized at Springfield, January 20, with Dr. George W. Menees, Springfield, president.

Barry County (Mich.) Medical Society.—This society was organized at Hastings, January 29, and asked affiliation with the Michigan State Medical Society.

Central Kentucky Medical Association.—At the annual meeting in Danville, January 17, Dr. William D. Powell, Harrodsburg, was elected president, and Dr. Steele Bailey, Stanford, secretary and treasurer.

Atlanta (Ga.) Medical Library Association.—A charter was granted to this association, January 30, on the petition of Drs. William S. Elkin, Virgil O. Hardon, E. Bates Block, and Floyd W. McRae, and Alexander W. Stirling.

Atchison County (Kan.) Medical Society.—This society was organized at Atchison, January 10, with Dr. J. F. Preston, Effingham, president; Dr. Charles S. Ferguson, Atchison, secretary, and Dr. Matthew T. Dingess, Potter, treasurer.

San Bernardino County (Cal.) Medical Society.—At a meeting held in San Bernardino, January 22, a new constitution and by-laws were adopted and application was made for affiliation with the Medical Society of the State of California.

Calloway County (Ky.) Medical Society.—At the annual meeting at Murray, January 15, Dr. E. B. Curd, New Providence, was elected president; Dr. J. T. Wall, Murray, vice-president, and Dr. Wildy H. Graves, Murray, secretary and treasurer.

Brashear Medical Society.—At the regular quarterly meeting in Chaplin, Ky., January 20, Dr. Squire B. Crume, Bloomfield, was elected president; Dr. J. W. Baird, Chaplin, vice-president, and Dr. Wiley Rogers, Taylorsville, secretary and treasurer.

St. Joseph (Mo.) Medical Society.—At the annual meeting, held January 14, the following officers were elected: Dr. Daniel Morton, president; Dr. Barton Pitts, vice-president; Dr. Louis J. Dandurant, secretary, and Dr. Charles Wood Fassett, treasurer.

Blackhawk County (Iowa) Medical Society.—At the annual meeting, January 9, in Waterloo, Dr. Elmer E. Dunkelberg was elected president; Dr. Thomas N. McManus, vice-president, and Dr. Fred W. Keehl, secretary and treasurer, all of Waterloo.

Alameda County (Cal.) Medical Society.—At the annual meeting held in Oakland, January 14, Dr. Oliver D. Hamlin was elected president; Dr. Jeremiah Maher, vice-president; Dr. Albert H. Pratt, secretary, and Dr. Charles A. Dukes, treasurer, all of Oakland.

Blue Earth Valley (Minn.) Medical Association.—At the quarterly meeting held in Blue Earth, January 13, Dr. Albert J. Franklin, Blue Earth, was elected president; Dr. S. C. Schmidt, Blue Earth, secretary, and Dr. Gustav H. Luedtke, Fairmont, treasurer.

Maury County (Tenn.) Medical Society.—The organization of this society was effected in January at Columbia, and the following officers were elected: Dr. M. M. Cook, Santa Fe, president; Dr. Hazle Padgett, Columbia, vice-president; Dr. Otey J. Porter, Columbia, secretary, and Dr. Russell S. Perry, Bigbyville, treasurer.

Newport (R. I.) Medical Society.—At the annual meeting, January 30, Dr. Christopher F. Barker was elected president; Dr. V. Mott Francis, vice-president; Dr. Mary E. Baldwin, secretary; Dr. Douglas P. A. Jacoby, treasurer; Dr. William S. Sherman, librarian; Dr. Harry J. Knapp, curator, and Dr. Charles W. Stewart, bacteriologist.

Bay County (Mich.) Medical Society.—At the annual meeting in Bay City, January 19, the retiring president entertained the members at a banquet. Dr. Everett A. Hoyt, Bay City, was elected president; Dr. George W. Moore, Munger, vice-president; Dr. Morton Gallagher, Bay City, secretary, and Dr. Charles H. Baker, Bay City, treasurer.

CHICAGO SOCIETY OF INTERNAL MEDICINE.

Meeting held Jan. 19, 1903.

The President, Dr. Edward F. Wells, in the Chair.

Streptococcus and Staphylococcus Bronchitis.

DR. JOSEPH M. PATTON read this paper. After referring to the classifications of bronchitis, and going exhaustively into the literature of the subject, three case histories, taken from a number of cases, were cited by the author to illustrate and support the occurrence of a form of bronchitis due to infection by streptococci or staphylococci, or both, and probably primary, which exhibit more or less characteristic features, and in some cases simulate the early clinical history of tubercular infections.

These cases did not present a history of a primary influenza, but exhibited marked physical signs of local or general bronchitis, with continuous temperature, persistent cough, occasional night sweats, loss of expansion, and, in some, modifications of pitch, which might be suggestive. The sputum showed streptococci and staphylococci. In one of the cases cited staphylococci alone were present. No influenza bacilli were present. These cases completely recovered in a few weeks.

The subjective symptoms are not sufficient for diagnosis. The physical signs may be only suggestive, especially in cases of staphylococcus infection, with lack of sudden onset, a tendency to localization, and the subacute character of the subjective signs, which much resemble the onset of tuberculosis, involving the terminal bronchial tract, the principal difference being the infrequency of apical localization. Dr. Patton called attention to the unsatisfactory results from the usual sedative or stimulating expectorant treatment, and remarked that the best results come from alterative medication, and the use of soothing and stimulating local medication by deep inhalation.

DISCUSSION.

DR. ARTHUR R. ELLIOTT stated that it has been his experience, in cases of bronchitis secondary to other organic lesions, particularly bronchitis, which develops in the later stages of nephritis and is secondary to myocardial diseases, in which pulmonary congestion and bronchial symptoms develop, that bacteriologic examination of the sputum occasionally shows the presence of streptococci. This infection, he thinks, must be largely accidental, and the secondary one invited by the low resistance of the tissues resulting from the primary disease.

DR. EDWARD F. WELLS said that it has been his practice for some years to make use of the iodid of potassium in small doses, giving, say, three or four grains four times a day for three days, for the purpose of increasing the amount of serum from the bronchial surfaces in the diagnosis of suspected cases of pulmonary tuberculosis. Numbers of cases of chronic bronchitis have come under observation under these circumstances. A number of them have been subjected to this and other methods of examination for a few months for some years. These cases have all been examined many times bacteriologically. He has made observations that are applicable to the paper read. *First*, there was a mixed infection in all cases of chronic bronchitis, staphylococci and streptococci being present in large numbers, also various other organisms, more especially the pneumococcus. *Second*, that while the treatment of such cases by sedatives, especially by opiates, has been quite unsatisfactory, the report made by patients invariably, after taking iodid of potassium, has been that they were benefited by it. Their cough has been rendered less frequent. He has not followed this sort of treatment, but would not be surprised if it should be a valuable remedy in all forms of bronchitis in which the cough is dry and frequent.

A number of cases of bronchitis have come under his observation during the last few months, in which bacteriologic examinations were made within twenty-four or forty-eight hours of the onset of the symptoms. These cases have had a very common symptomatology—slight chilliness, a feverish condition, headache, aching pains, stuffy condition of the nostrils, at first a serous, then mucous and purulent discharges from the nostrils, the inflammation extending down and accompanied by a considerable amount of tonsillitis, terminating, within twenty-four or forty-eight hours, in bronchitis, with slight expectoration. The nasal discharges have been examined and cultural experiments made of such discharges as have been obtained early from the bronchial tubes. The cases, without exception, showed bacilli in large numbers, and by the time the secretions became purulent the infection was mixed, mainly staphylococci and streptococci being present. In the majority of these cases particles of sputum from different parts, when put in different culture boxes, showed almost pure staphylococcus and streptococcus, apparently showing that in different parts of the respiratory tract one or the other of the germs had located, and had spread by the infection in that locality, but both were found present generally.

DR. PATTON, in closing the discussion, stated that the cases which he cited were selected with special reference to discarding that class of cases that had shown absolutely no subjective or objective sign of congestion or inflammation of the upper respiratory tract, in which the infection seems to have begun in the bronchial area, and it is here that streptococci and staphylococci are most frequently found. The question of principal interest to him is as to whether these infections, acute bronchitis, or subacute or chronic bronchitis, as the case may be, are not preceded by an influenzal condition of the upper respiratory tract, because those that have been preceded by such a condition have uniformly shown a primary influenzal infection, followed by secondary development of the other organism. But in those cases that have not been preceded by an influenzal condition, it is a question whether they are not primary infections with staphylococci or streptococci, either by inhalation infection, by exposure, or something of that kind, giving a type of bronchitis which is somewhat different in its symptomatology and in its reaction to medication from the ordinary types of secondary bronchitis, even though one may find the same organisms in the secondary bronchitis, differing in its symptomatology from the fact that there is a more irritating cough, continuous and moderately high temperature, night sweats, indications of physical signs resembling closely the early signs of tuberculosis in the streptococcic form; in the staphylococcic form, a lower temperature, but just as continuous, with less cough, less expectoration, a more localized area involved, but a condition which resists the ordinary expectorant medication just as persistently as does the other form.

Cockroaches as Conveyers of Typhoid Infection.

DR. ROSA ENGELMANN read a paper on this subject. She gave the history of a house epidemic of typhoid fever which, in the opinion of Dr. Edward F. Wells and herself, was spread by cockroaches. She could find no other record of such conveyance in the literature. Flies, mosquitoes, fleas, bedbugs and cockroaches belong to the same large family and order of insects. All but the cockroach have been demonstrated to be not alone the active or intermediary hosts, but also accidental carriers of various diseases, including typhoid fever and its allied disorder, bubonic plague.

In October, 1902, on the complaint of Dr. Wells, the essayist was instructed by the health department to investigate a house epidemic of typhoid fever, which in five months had claimed as many victims in one large, eight-flat, well-constructed apartment building. A similar neighboring building, furnished in common with an artesian well-water supply, general and janitor service, was and had been free for two years of any sickness. Another peculiarity was the fact that the typhoid cases, with one exception, were confined to the south tier of apartments and occurred in four families. Dr. Engelmann detailed the cases and the food and hygienic conditions of the families. The cases began on the first floor in June and extended upward, the last occurring on the fourth floor in October. The tenant on the fourth floor, south flat, complained during the summer for relief from a perfect pest of cockroaches. They were on the food and in the beds and all over the drawing room, so that this family was having daily and deadly raids on these unwelcome invaders, which not only permanently installed themselves in every room, but came up in additional hordes in the clothes baskets when brought up from the basement. The place was literally alive with cockroaches. Why was this basement overrun with them, while the neighboring basement was exempt? The people were well and every flat occupied in the second apartment building, while in the first one there was sickness in two families, with consequent neglect of housekeeping. The second closed flats above next became ridden with vermin and communicated this condition to the top flat from which the greatest complaint came and in which the last case of typhoid fever appeared.

The etiology of the first case is uncertain, although it can probably be ascribed to culinary and toilet use of the city water, which, at intervals during the spring and early summer, had been turned into the house mains by the janitor when his artesian well pump broke down. He also at monthly intervals turned on the city water into the tank in order to wash it out, for it was less labor to scrub it with city water than to carry up the artesian water from the pump level to a sixty or seventy-foot tank elevation. Not only did the artesian well tank water become contaminated, but the house mains. This state of affairs ceased with the employment of a new janitor later in the summer, who notified tenants when the city water was turned into the house mains. If the infection was due in all these cases to the water supply, why was there no further incidents of the disease in the other twelve families, and why was it almost confined to the tier directly over the first case? The artesian well water, freshly pumped, and the tank supply were examined twice in October and found to be free from typhoid germs. The pump connections, piping and drainage were perfect, as were the plumbing and sewage connections. On repeated complaints of the tenants during the summer the catch-basins were finally cleaned in the fall, but probably not until after the cockroaches had carried sewage, typhoid infected by case 1, or possibly case 2, to the food supplies of the other afflicted families. By October the vermin were also beginning to be exterminated by the efforts of professional exterminators, and no more cases appeared. During this time the adjacent building had been comparatively free from cockroaches.

DISCUSSION.

DR. JOSEPH M. PATTON thought there was nothing strange or improbable in the supposition that cockroaches may carry typhoid infection, because they carry nearly everything else they come in contact with, and they are so numerous and frequent and such pests about apartment buildings in large cities that if it were only once thoroughly established that they are carriers of typhoid infection, it would have an immense hygienic value, and undoubtedly would remove a source of infection that is dangerous, and which is practically continuous in all buildings that are steam-heated in cold weather.

DR. EDWARD F. WELLS said that in the families resident in these two flats the surroundings of all seemed to be alike, with the exception of the presence of numerous cockroaches in the flats mentioned by the essayist. All of them had the same water supply. Dr. Engelmann made a number of visits to the house, carefully investigated the flats, and had given the results of her observations in regard to cockroaches being a prominent factor in the conveyance of typhoid fever. The tenants of the building complained of the cockroaches, not having in view any hygienic features except they were disgusted with their presence.

DR. ENGELMANN, in closing the discussion, said that possibly the most instructive thing in the future would be the more careful investigation as to the presence or absence of typhoid bacilli in the gastrointestinal canal of the cockroaches. Very recently Japanese investigators have found the pest bacillus, and have shown that bedbugs and fleas are active or intermediary hosts of the pest bacillus. She thought the same line of investigation might be applied to the cockroach as a host for this or various germs.

Therapeutics.

[It is the aim of this department to aid the general practitioner by giving practical prescriptions and, in brief, methods of treatment for the diseases seen especially in every-day practice. Proper inquiries concerning general formulae and outlines of treatment are answered in these columns without allusion to inquirer.]

Acute Myocarditis.

Lemoine, in an abstract in *Amer. Med.*, states that strophanthus is the best remedy in the treatment of acute myocarditis when a heart stimulant is indicated. He recommends it combined as follows:

℞. Ext. strophanthi .....gr. 1/12 | 005
Syr. acaciæ q. s. ad.

M. Ft. pil. No. i. Sig.: One such pill morning and evening.

In case of collapse strophanthus should be associated with a rapidly diffusible stimulant such as the following:

℞. Camphoræ .....gr. viiss | 50
Spts. etheris.
Aq. destil., āā 3i 4

M. Sig.: Fifteen to forty-five minims to be injected subcutaneously in twenty-four hours.

Quinin to Children.

The following combinations, containing quinin, as noted in *Pract. Drug. and Review*, are recommended in administering that drug to children:

℞. Quininæ sulph. .....gr. x | 65
Aquæ (acidulated) .....m. lxxv 5
Mellis albi 3x 40

M. Sig.: One small teaspoonful every two or three hours as indicated; or:

℞. Quininæ hydrochloridi .....gr. ivss | 27
Ext. glycyrrhizæ .....gr. xlv 3
Aq. destil. 3x 40

M. Sig.: To be given in divided doses according to the age of the child; or:

℞. Quininæ sulph. 3i 4
Acidi citrici
Syrupi simplicis
Syrupi aurantii, āā .....3iiss· 10
Aquæ destil. 3v 20

M. Sig.: Ten drops in two ounces of water to which are added 45 grains of sodium bicarbonate and drunk while effervescing.

As a suppository the following:

℞. Quin. sulph. .....gr. iss to viiss | 09-.50
Olei theobrom. q. s.

M. Ft. suppos. No. i. Sig.: One to two suppositories daily.

Bronchitis and Bronchopneumonia in Children.

Mitchell, in an abstract taken from *Archives of Pediatrics*, recommends, in the treatment of bronchitis and bronchopneumonia of children, that the feeding, clothing, bathing and exercise be carefully watched. And while prophylactic medicinal treatment is often necessary, any drugs which tend to disturb

the appetite or digestion must be discarded. He recommends the cotton jacket instead of the heavy poultice. Antipyretics should never be used to control the fever, the gradually-reduced bath being substituted.

For the cough, steam inhalations, simple or medicated, are of value. When the cough is harsh and dry, opiates may be given. In subacute or chronic cases, creosote or guaiacol carbonate are of benefit. Strychnia may be used as a heart stimulant.

Obesity.

The following outline of treatment of obesity is suggested by M. Kisch in *Med. Press.* When the accumulation of fat is in the lumbar or abdominal regions, besides the usual diet treatment the following is recommended locally:

℞.	Pot. iodidi	3i	4
	Iodi	gr. vi	35
	Vaselini	ʒi	30

M. Sig.: To be rubbed in night and morning over the lumbar region, and the parts covered with a large compress steeped in a solution of aluminum acetate:

℞.	Plumbi acetatis	3ii	8
	Aluminis	3ss	2
	Aquæ	ʒviii	240

M. Sig.: Locally on compresses. A sheet of oiled silk should be placed over the compress.

For friction to the abdominal wall the following ointment is recommended:

℞.	Pot. iodidi	3ii	8
	Aceti scillæ	ʒviii	240

M. Sig.: Apply locally.

Capsicum.

Sir James Sawyer, according to *New York Med. Jour.*, recommends the non-alcoholic ethereal tincture of capsicum as a splendid local application in the treatment of subacute and chronic gout, muscular and chronic rheumatism, and in certain forms of bronchitis. He prefers ether to alcohol because of its action on the sebaceous secretion of the skin, and it is easily mixed with turpentine and other essential oils. The following combination is recommended by him as an excellent rubefacient:

℞.	Tinct. capsici (ethereal)		
	Sol. ammoniæ		
	Spts. terebinthinæ		
	Olei lini, āā	ʒi	30

M. Sig.: Apply locally to the affected parts.

Scabies.

The following combination is frequently recommended in the treatment of scabies:

℞.	Menthol	gr. xl	2	65
	Ichthyol	3iv	15	
	Calcii sulphid.	3i	4	
	Sulphuris	3ii	8	
	Lanolini			
	Oleo olivæ, āā, q. s. ad.	ʒiii	90	

M. Sig.: To be applied locally.

W. B. Brown, in the *Post-Graduate*, recommends that the skin be well washed with soap and water and scrubbed with a brush. The following ointment should then be applied twice a day for three days:

℞.	Potassii carb.	ʒss	15
	Sulph. sublim	ʒi	30
	Adipis	ʒiv	120

M. Fiat ung. Sig.: Apply locally.

The same author recommends the following in the treatment of sycosis barbæ (barber's itch):

℞.	Bismuthi subnit.	3ii	8
	Acidi salicylici	gr. xv	1
	Adipis	ʒi	30

M. Sig.: Apply locally; or:

℞.	Ung. hydrarg. oxidi rub.	3ii	8
	Ung. sulphuris	3iv	15
	Ung. zinci oxidi	3ii	8

M. Sig.: Apply locally and bind on with a bandage at night.

Gonorrhea.

The following combination is recommended by Joseph Webb, in the *Med. Summary*, for the treatment of gonorrhea:

℞.	Acidi borici	3iss	6
	Tinct. iodi	3ii	8
	Glycerini	ʒi	30
	Aquæ destil.	ʒiv	120

M. Sig.: To be used as an injection morning and evening.

Stubborn Bronchitis.

In the same periodical J. J. Caldwell recommends the following mixture for the relief of a stubborn bronchitis:

℞.	Heroin		
	Ammon. hypophos., āā	gr. ii	12
	Tinct. hyoscyami		
	Syr. white pine, āā	3i	4
	Syr. tolutani	ʒi	30
	Glycerini q. s. ad	ʒiv	120

M. Sig.: Shake, one teaspoonful three times a day.

The white pine, according to the author, serves as a tonic to the throat and bronchi and allays the night sweats. The balsam of tolu is an aromatic stimulant. The heroin relieves the irritability of the respiratory tract, being a valuable antispasmodic.

Ginger.

Ginger, according to W. O. Bunnell, in *Med. Council*, is a common but useful remedy in a great many different conditions. It is a stimulant, rubefacient and sialogogue. When chewed, according to the author, it increases the flow of saliva and acts as a stomachic and carminative by increasing the flow of the gastric juice and exciting muscular activity of the alimentary canal. It may be used in conjunction with other preparations and astringents to check diarrhea and dysentery.

Forty to 50 grains in a cup of hot water are recommended to be taken at bedtime in order to check a cold. In the treatment of dyspeptic conditions it may be given in 15 or 20-grain doses in hot water every two or three hours.

He recommends it as a remedy in violent headaches by forming it into a plaster with hot water. The same is of service in swollen joints, lumbago, pain in the stomach or bowels.

Oil of Cloves.

W. A. Briggs, in *Amer. Med.*, recommends very highly the use of oil of cloves in surgical dressings. In punctured wounds, such as by nails, he packs the wound with sterilized gauze saturated in pure clove oil. The same procedures are carried out in treating localized abscesses, first evacuating the pus and then packing the cavity with gauze saturated with dilute oil of cloves. He uses it in disinfecting his hands in obstetrical cases. He also recommends it as an antiseptic dressing for the umbilical cord by saturating the dressings with a 30 per cent. solution of clove oil in olive oil, changing the gauze each day. The advantages claimed for these purposes as set forth by the author, are:

1. It is practically non-toxic. No constitutional disturbances have ever been observed.
2. It is a powerful antiseptic and local analgesic.
3. It affords rapid, simple and ready means of disinfecting the hands and keeping them in an antiseptic state. The skin is rather sensitive at first, but rapidly becomes accustomed to it and remains in good condition.

Burns.

Biddle, in *Penn. Med. Jour.*, states that he applies locally, in the treatment of burns, a mixture composed of lead carbonate, pulverized acacia, linseed oil and sodium bicarbonate. This should be made thin enough to spread easily on soft cloth. He states, after applying this treatment, very few scars are left. If the outer skin has been devitalized he removes it at once with scissors in order that the dressing may be more directly applied to the diseased areas. The dressings are frequently changed, and if the granulations get too high, salicylic acid should be dusted over the surface. The lead dressing is usually applied for about ten days.

He recommends that skin grafting be done early in those cases where much destruction of tissue has occurred or in

parts near tendons where contractures are most apt to follow. He states, owing to the addition of the acacia to the lead mixture, that he has never seen serious absorption of the lead take place. If symptoms of lead poison should occur he gives the usual doses of magnesium sulphate. If diarrhea sets in, due to intestinal inflammation, he administers salol, bismuth subnitrate or creosote.

Diabetes.

Yeo, in *Clin. Ther.*, recommends the following combinations to be employed in the treatment of the different conditions in diabetes:

AS A MOUTH WASH.

℞.	Sodii boratis Pot. chloratis, āā.....3i	4	
	Glycerini Mucil. acaciæ, āā .....℥i	30	
	Aquæ q. s. ad.....℥viii	240	

M. Sig.: To be used as a mouth wash; or:

℞.	Sodii boratis 3ii	8	
	Tinct. myrrhæ .....℥ss	15	
	Aquæ q. s. ad .....℥vi	180	

M. Sig.: To be used with an equal quantity of warm water.

FOR THE ITCHING.

℞.	Sodii sulph. .....℥ss	15	
	Aquæ .....℥vi	180	

M. Fiat lotio. Sig.: Apply locally; or:

℞.	Acidi hydrocyanici dil. 3i	4	
	Glycerini .....℥i	30	
	Aquæ q. s. ad.....℥vi	180	

M. Fiat lotio. Sig.: Apply locally.

SYSTEMIC TREATMENT.

℞.	Lithii carb. .....gr. xxx	2	
	Sodii arsenatis .....gr. i		06
	Ext. gentianæ .....gr. xv	1	

M. Ft. pil. No. xx. Sig.: One pill night and morning; or:

℞.	Iodoformi .....gr. xv	1	
	Ext. lactucarii .....gr. xv	1	

M. Ft. pil. No. xx Sig: One pill three times a day; or:

℞.	Antipyrini 3iiss	10	
	Saccharini .....gr. iii		20
	Sodii bicarb. .....gr. ii		12
	Infusi coffeæ .....℥v	150	

M. Sig.: One tablespoonful two or three times a day.

Medicolegal.

Duty to Take Seamen Into Port for Surgical Aid.—The U. S. Circuit Court of Appeals, Ninth Circuit, says, in the case of the *Iroquois*, that it has no doubt that it was the duty of the master of that vessel to bear away to some port of distress as soon as possible after one of its seamen had accidentally, and without fault of his own or fault of the ship, sustained a fracture of two ribs and both bones of his right leg below the knee. The vessel was at the time of the accident a few miles to the southward of Cape Horn. The master, whose only knowledge as to the treatment of fractures had been derived from his own experience at some time previous when he had received treatment from a surgeon for a fractured leg, set the seaman's leg as well as he could, bound it and placed it on a cushion in order to elevate it above the body, and instructed the steward to give the injured man gruel, mush and other light food. The broken ribs healed, but the bones of the leg failed to unite, and after the vessel reached San Francisco the leg had to be amputated a little below the knee. The court holds that it was no excuse that the master was ignorant, or that he believed the broken leg was healing properly, and for that reason thought it unnecessary to bear away from his course. Nor was he excused by the fact that the injured seaman at the time made no complaint of the treatment he received, and made no demand to be taken to a port of distress. The duty of the master to him was a positive one. He had been disabled while in the service of the ship, and without any fault on his own part. By the maritime law he was entitled to be healed at the expense of the ship. His injury was a serious one, and the master must be presumed to have known that it required careful and scientific treatment.

Not Entitled to License Without Taking Examination.—The Supreme Court of South Carolina holds, in the case of Moore vs. Napier and others, that the petitioner, who received a diploma from the South Carolina Medical College, but who studied the course for only three years, was not entitled to a writ of mandamus requiring the board of medical examiners to issue to him a license to practice medicine without standing an examination before the board as to his qualifications and knowledge of medicine. It appeared that when he matriculated as a student of the South Carolina Medical College the course of study established for graduation was only three years; that before receiving his diploma the South Carolina Medical College established a four years' course of study, commencing with the collegiate year of 1901; and that, as above stated, he took only a three years' course. The change in the course of study from three to four years was apparently made to enable graduates holding diplomas to receive the benefit of the amendatory statute of Feb. 15, 1901, exempting from the necessity of standing an examination before the board of medical examiners as to qualifications and fitness "regular graduates, holding diplomas issued by any college of established reputation in this state which has a four years' course of instruction and a standard of not less than 75 per cent. on examination." The court holds that it was the manifest intention of the amendatory act to make the exemption stated when satisfactory evidence of the standing of the college is made to the board of medical examiners, and when the graduate has studied the course for four years. And it says that, in the exercise of its discretion, it will refuse the writ of mandamus when the effect of granting it would be to violate the intention of an act of the legislature.

Admissibility of Radiograph on Its Own Merit.—The Supreme Court of Nebraska holds, in the malpractice case of Carlson vs. Benton and others, that, to constitute a foundation for the introduction of an *x*-ray photograph in evidence, it is not essential that it appear that it was taken by a competent person, nor that the condition of the apparatus with which it was taken and the circumstances under which it was taken were such as to insure an accurate picture, provided that it has been shown by the evidence of competent witnesses that it truly represents the object it is claimed to represent. The discretion of the trial judge in the reception of such evidence is not absolute, and may not be exercised arbitrarily; and where the evidence as to the accuracy of the photograph leaves no room for a difference of opinion, its exclusion on the ground that a sufficient foundation has not been laid is an abuse of discretion. In this case an *x*-ray photograph of an injured leg, taken after the injuries had been treated by the parties sued, was offered in evidence. The uncontradicted testimony of three surgeons left no room for a difference of opinion as to the accuracy of the photograph, and it is held that to exclude under such circumstances, on the ground that a sufficient foundation had not been laid, was an abuse of discretion. The novelty of the *x*-ray photograph, it is said, does not extend to the rules governing its reception in evidence. Maps, photos, drawings and models are admissible in evidence when it is shown that they fairly represent the object or objects under investigation. There is no good reason why the same rule should not apply to photographs of this character. Lastly, it was urged that, whatever error there might have been in the exclusion of the photograph, it was error without prejudice, because there was no conflict in the testimony on the question of the existence of a dislocation and improper union of the bones. But it is answered that, if the record bore out this statement, it would not be safe to say that the exclusion of the photograph worked no prejudice to the party suing. The condition and position of the bones of his leg after it had been treated were among the matters to be investigated by the jury. It is hardly possible to convey such matters to the average mind as clearly by oral testimony as it may be conveyed by means of a photograph. The verdict of the jury in favor of the parties sued was general, and it would be rash to assume that it was not influenced by the exclusion of the evidence in question.

Current Medical Literature.

AMERICAN.

Titles marked with an asterisk (*) are abstracted below.

Medical News, New York.

January 31.

1 *The Limitations of the X-Ray in the Treatment of Malignant Tumors. William B. Coley.
2 A Plea for a Neurologic Hospital in New York. L. Pierce Clark.
3 *The Negro as a Criminal and His Influence on the White Race. Louis Edelman.
4 *Affections of the Labyrinth Resulting from General and Organic Disease. Thomas R. Pooley.
5 *Is Any Diseased Condition Necessarily Self-limited? Edwin R. Maxson.

1. **The X-Ray.**—Coley gives his experience with the *x*-ray. He believes that the interests of both science and our patients will be best subserved by strictly limiting the method to inoperable cases and to cases after operation, as a prophylactic measure. The method is still on trial, and it is to be hoped that we may be able to give the *x*-ray its proper place soon, but for the present we should give it an impartial study.

3. **The Negro as a Criminal.**—Edelman points out the great increase of crime in the negro, which he attributes to slavery, to ignorance and to environment. He thinks the educated negro does not become a criminal. What the race needs is labor. Lynching has a bad effect on the white race; it is no way of meeting the conditions. He thinks the proper method would be the establishment of convict farms where the negro criminal and idler could be sent and made to be self-supporting.

4. **Labyrinthine Disease.**—Pooley's article is largely a review of the literature and is quite an extensive discussion of the subject.

5. **Self-Limits of Disease.**—Maxson doubts whether any disease is necessarily self-limited, and gives his experience with typhoid as an illustration. He has been able, by using antiseptics, cathartics, warm baths, and regulated diet and tonics to arrest the disease and even partially abort it. He believes that many so-called contagious diseases originate *de novo* in individuals from bad environment and habits, and without such propagation of many of them would be almost impossible.

6 *A Note on the Anatomy of the Perirenal Fatty Tissue. W. W. Keen.
7 *Twelve Cases of Malignant Disease Treated by the Roentgen Rays. Henry P. Moseley.
8 *Some Notes on Pollacci's New Method of Detecting Albumin in the Urine. Gordon Lindsay and William J. Gies.
9 *Tuberculous Peritonitis. A. E. Halstead.
10 *Chronic Bilateral Parotitis Among the Insane, with a Detailed Account of Five Cases. Douglas Symmers.
11 *Tea and Coffee Intoxication. Emil King.
12 *The Natural Struggle of Mankind Against Contagious Disease. Claude du Bois-Reymond.

6. **Perirenal Fatty Tissue.**—Keen calls attention to the fact that there are two distinct layers of fatty tissue surrounding the kidney, one which should be called the transversalis layer of fat and the second the proper perinephric fat or fatty envelope of the kidney. In operating on the kidney so soon as the fat bulges through the incision, if it is carefully cut or torn through, gradually deepening the incision or tear, a distinct interval between these two layers will be found. A layer of connective tissue, then a second layer of fat presents itself. He has consulted over a score of anatomies and found this mentioned in but one book, Da Costa's "Modern Surgery," and the fact was communicated to the author in this case by himself.

7. **The X-Rays.**—The conclusions from twelve cases of malignant disease treated by Moseley are given as follows:

1. The small superficial cases of malignant disease seem to be most susceptible to this method of treatment.
2. The relief of pain is a very prominent feature of the Roentgen ray treatment, and is often noticed after the first exposure. In cases which have not progressed too far, it is almost possible to promise the anesthetic effect.
3. It is impossible to determine from our present knowledge without trial what cases will be favorably influenced by treatment, but patients should be warned not to be too hopeful.
4. The danger of burning is a real one. Patients should appreciate the possibility of it before treatment is started, although with precautions it may be avoided. In hospital work when the operator is doing much Roentgen ray work, the greatest precaution should be exercised in the care of his own face and hands. The apparatus should be arranged so that all changes in the tube necessary to be made while it is running can be accomplished by switches or mechanical devices so placed that the operator can control them at a distance of 12 or 15 feet from the tube.

8. **Pollacci's Method for Albumin Detection.**—The original description of this method appeared in the *Schweizerische Wochenschrift für Chemie und Pharmacie* (1901, xl, p. 168). The formula is given as follows:

A. 1 gram tartaric acid
   5 grams mercuric chlorid } dissolved in 100 c.c. water.
   10 grams sodium chlorid
B. Solution A + 5 c.c. formaldehyd (40% solution).

Solution B. is used for the detection of albumin as in Heller's test, care being taken to stratify the solutions and prevent their admixture. Should a white zone appear at the line of contact of the two fluids the urine contains pathologic albumin. Pollacci claims that this is more delicate and sensitive than the Spiegler reagent or than other methods. Lindsay and Gies have examined this method and conclude as follows:

1. Pollacci's reagent readily precipitates various proteids—simple, compound and albuminoid.
2. The test is too delicate for ordinary clinical purposes, since the normally occurring urinary proteids are precipitated by the reagent.
3. Various nonproteid substances occurring in the urine in health and disease are probably also precipitated by the reagent.
4. The latter possesses little or no advantage over Spiegler's fluid.

9. **Tuberculous Peritonitis.**—Halstead discusses the condition and its literature with special reference to laparotomy and the benefit derived. The operation itself is not entirely devoid of danger as shown by a case he here reports. The evil outcome was probably due to a toxemia, the toxic substances being probably liberated from changes which occurred consequent on operation.

10. **Chronic Bilateral Parotitis.**—Symmers reports five cases occurring in the insane and discusses their probable causes. The first one he thinks was a stigma of degeneration, the second, third and fourth had a history or suggestion of syphilis and in the fifth there was a history of ulcerative laryngitis which may have been responsible.

11. **Tea and Coffee Intoxication.**—King calls attention to the tea and coffee inebriates and reports two cases. He thinks we should bear in mind this possibility in the study of our cases, especially if the symptoms are such as would suggest it. In the treatment the essential point is to stop the habit. Other methods are only symptomatic. It does not seem to lead to organic disease like alcohol, though in the insane asylums of Ireland tea excess is considered as a prominent cause of mental disorder.

12. **Contagion.**—In this special article, Du Bois-Reymond uses a sort of mathematical method in the study of the spread of disease by contagion, especially tuberculosis, which he considers practically non-contagious as compared with such diseases as measles, which he also uses as an illustration. What we need in the fight against tuberculosis is not so much restoring the health of the individual as it is to decrease the number of predisposed individuals. We can not kill them, but the best thing to be done is to keep in mind the prophylaxis of the disease, especially in children. The entire rising generation ought to be trained from birth upward to the use of fresh air, bathing, sunshine and breathing gymnastics, and individual dwellings converted into sanatoriums.

14 *Tropical Dysentery. Charles F. Kieffer.
15 *Insanity Among Soldiers of the American Army in the Philippine Service. A. B. Richardson.
16 *The Relation of the Prefrontal Lobes to Mental Function. Charles W. Burr.
17 Case-Book Record of 183 Operations on the Mastoid Bone. Levi J. Hammond.

14. **Tropical Diseases.**—This second lecture by Kieffer is devoted to the various forms of dysentery, endemic or amebic, epidemic or bacillary, sporadic, traumatic, etc.

15. **Insanity Among Soldiers.**—Richardson gives the results of experience at the Government Insane Asylum with returned insane soldiers from the Philippines. Only 260 out of 396 cases sent home as insane reached the hospital. Nearly all the remainder were found to be practically recovered when they landed or recovered while at the Presidio, California, and were returned to duty. A few were discharged for disability, and a very few died. Out of the total of those received at the hospital, 187 were discharged as recovered up to June 30, 1902, and 14 discharged as improved, 6 died and 112 remained under treatment. The recovery rate is therefore high. The form of the disease was largely melancholia, which Richardson considers in a large majority of cases should be included in the Kraepelin classification as exhaustion and infection psychoses. Nearly all of the cases had been in service only one or two years, and there have not been half a dozen veteran soldiers received since the commencement of the Spanish-American war. He considers that the popular impression of the prevalence and unfavorable character of insanity among American soldiers in the Philippines has been greatly exaggerated.

16. **The Prefrontal Lobe.**—The relation of the prefrontal lobes to mentality is discussed at some length by Burr, who goes over the opinions of others and reports a case of tumor of this region. He does not derive the opinion from his study that the prefrontal region is the center of mind, but favors the view that it is in closer relation with the mental processes than some other parts of the brain.

26 A Case of Eclampsia. P. P. M. Jorgensen.
27 The Treatment of Diseases of the Liver. H. Richardson.

18. **Syphilis.**—Douty's article is a plea for the open-air treatment for the first six months or a year in many cases, and if possible for two years. He has noticed that a large proportion, 30 per cent. or more, of men patients who have phthisis were syphilitic, and other observers report similar figures. He thinks that a syphilitic should certainly devote one year to an open-air life, the Alpine region with its pure air, and stimulation of metabolism is especially favorable for such cases. In his experience well-to-do persons who led an out-of-door life generally suffered lightly from their syphilis.

20. **The X-Ray.**—Beck believes in idiosyncrasy as a cause for *x*-ray injuries, and in the tentative use of the rays to determine this. He advises a first exposure of five minutes with a soft tube and light just strong enough to show the carpus of the operator black without structural details. After a week, repetition of the exposure, lasting ten minutes. If after the third exposure, two weeks from the first, no reaction has occurred, the patient is apparently not susceptible. During the tentative exposures the distance from the tube should be five inches and the vicinity of the irradiated area should be protected. He reports and illustrates a case showing the effects of the *x*-rays in malignant disease, and in such cases he did not use the tentative exposures, applying the tube as near as possible to the diseased area, not exceeding two inches. After a slight erythematous reaction has occurred, within the immediate vicinity of the growth, the distance is increased for the following seance, the rays reaching a larger surface. When this widened field also becomes erythematous, the rays should be stopped for a few days until the erythema shows signs of disappearance, though it is not advisable to wait until the last little sign of dermatitis has vanished. He thinks the farther the carcinomatous infiltration has extended, the more resistance to dermatitis exists. This non-susceptibility seems to be greatest in the fibroid variety of carcinoma. With extensive ulceration, causing retention of pus, the irradiation should be continued until the area is fully exposed and the necrosed tissue is curetted away. Without this, the power of the rays is not only inhibited, but toxemia from local decomposition is added to cachexia. He does not consider that the production of dermatitis in the treatment of malignant disease is desirable, but with our present means, the use of the rays should be thorough enough to produce dermatitis, which is unavoidable. His experience shows that whenever the dermatitis has appeared the size of the growth has diminished, edema and pain have decreased, and the general condition has been improved. Of course, in operations for hypertrichosis or for similar superficial growths the condition is somewhat different. In conclusion he calls attention to the advisability of prophylactic irradiation shortly after removal of malignant tumors.

22. **Therapy of the Air and Light Treatment.**—Bleyer thinks that exposure of the nude body to the light has a decided effect on the action of iron given internally, greatly assisting its remedial action.

23. **Spina Bifida.**—Griffith reports the case of an infant in which an operation was performed for spina bifida at the age of less than 4 months. The child was kept in the inclined position, head down forty degrees, during the operation without any bad effect. The general anesthetic used was ether. The child seemed to do well for three of four days, during which the inclined position was maintained, but then some threatening symptoms appeared, which were accounted for by the extensive drainage of the cerebrospinal fluid. The cause of death was an accident, the child falling from its mother's arms. Griffith thinks, from a study of the case, that in the future he would be justified in attempting more or less active operative procedures, bearing in mind the delicacy of the subject. He is especially impressed with the value of the inclined position in the treatment of these cases. Slung by the legs, assisted by the child's nightgown, drawn together below the feet, thus equalizing pressure, the child will be found to have adequate movement on the face or side. Nursing and all necessary toilet procedures can be readily accomplished in this position, and if so held until healing is well established, greater hopes for a successful issue seem possible. To overcome the siphon action of dressings, it would seem advisable to hermetically seal the urea surrounding the wound from the rest of the dressing by means of rubber tissue dissolved about its edges with chloroform, or by collodion upon cotton.

31 *The Open-air Treatment of Syphilis. E. H. Douty.
32 A Report of Eleven Cases of Morbus Coxæ Senilis. W. E. Blodgett.

28. **Chylous Ascites.**—In the case reported by Comey the cause of the trouble was a chronic lymphangitis, involving some eighteen inches of the thoracic duct and completely occluding it. The pathologic part of the article is written by McKibben, who seems inclined to suggest the tubercular origin and that it may have been due to the revival of some old focus of infection.

29. **Lesions of the Tibial Tubercle.**—The following are the conclusions of Osgood's article:

The adolescent tibial tubercle, from its situation and mode of development, is susceptible to injuries, especially in athletic subjects. These lesions are usually caused by a violent contraction of the quadriceps extensor. Fracture and complete avulsions of the tubercle are rare, cause loss of function, and are easily diagnosed, usually clinically and always by means of the *x*-ray. Avulsions of a small portion and partial separation of the tubercle are more common. They do not cause complete loss of function, but without treatment, long-continued serious annoyance. The diagnosis should

be made by a combination of the clinical and *x*-ray pictures, and before the latter are accepted as evidence both knees should be skiagraphed and accurate technic observed.

30. **The Side Chain Theory.**—Thayer describes the modern theories of immunity, especially the side chain theory of Ehrlich, and remarks in conclusion in regard to his contention that every toxin, every parasitic bacterium and every variety of animal cell has its own specific affinity in side chains of the corporeal protoplasm, that if this be granted it is conceivable that under favorable conditions immunity may be established against anything. One has only to irritate the cell in the proper way and it will furnish specific side chains for every irritant.

36 Fourteen Cases of Smallpox from the Buffalo Epidemic of 1901-1902. D. E. Wheeler.

33. **Formaldehyd in Septicemia.**—Barrows reports a case of puerperal streptococcus septicemia in which he used two intravenous infusions of 500 and 750 c.c. of a 1 to 5,000 aqueous solution of formalin with remarkably good results. He quotes from Maguire as to the safety of such injections, often in much larger proportions than those above given, and also his authority that in the quantity of 1 to 200,000 it is an efficient germicide. Barrows cautions against the indiscriminate use of the method where proper blood cultures are lacking. The success will depend on its correct and scientific application. The case reported is that which has caused a good deal of comment in the daily press, and has been utilized rather sensationally by lay reporters. See editorial in THE JOURNAL, February 7.

34. **Rectal Fistula.**—Rose reports a case of rectal fistula completely cured by the use of applications of carbonic acid gas, and offers the case as an illustration of a probably valuable treatment in such conditions.

St. Louis Medical Review.

January 24.

37 *Corsets and Their Cause: A Case in Point. Fayette C. Ewing.

37. **Corsets.**—The charges against the corset and tight lacing are, in a measure, opposed by Ewing, who reports the case of a young lady who had worn corsets since the age of 8, and had a typical fashion-plate figure, a magnificently developed bust and middle chest and a pronouncedly tapering lower chest, with hooped ribs extending clear down to the liver and crest of the ileum. The liver was displaced downward two inches. The breathing capacity was 32 to 34 inches in the upper chest, somewhat more in the middle and only 23½ to 26 in the lower chest. The expansion of the middle chest, he remarks, is specially interesting, in light of our knowledge that the region is usually incapable of as much expansion as here shown in the average slender woman. The lady, according to her accounts, never suffered from any ill health, though she had a cardiac murmur without any history of rheumatism. She had never been in the habit of practicing deep inspiration. Ewing discusses the cause of the popularity of the corset, and thinks it is in the doctrine of antithesis. Men and women instinctively admire their opposites.

44 *Report of Cases Treated with Roentgen Rays. (Continued.) Wm. Allen Pusey.
45 Diseases of the Pulmonary Vessels. Albert Abrams.

44. **The X-Rays.**—Pusey continues his report of cases treated with the *x*-rays, giving an account of a number of consecutive cases of epithelioma, all of which he thinks can be considered as successes. He can not say that recurrences will not occur, but the character of the scars do not indicate that this is likely, and if they do occur *in situ* there is every reason to believe their management will be less troublesome. He does not believe any other treatment can show such results, and his experience in epitheliomas has given him great confidence in the method. Thus far he has had no case in which the disease has failed to yield, and usually promptly. The scars are soft, free from induration, smooth, and of the color of the normal skin or white, and absolutely healthy looking, in fact there is almost no scarring.

52 *Polypoid Growths in Children vs. Prolapse. Lewis H. Adler, Jr.

46.—See abstract in THE JOURNAL, xxxix, p. 930.

49.—Ibid.

50. **Shoulder-Joint Amputation in Carcinoma.**—Roberts calls attention to his former advocacy of disarticulation of the arm at the shoulder joint as the routine method in all cases in which axillary carcinoma occurred secondary to excision of the breast for malignant disease. He reports a case operated on in 1899, in which the arm was ultimately removed, but the patient died. He had hoped to save the limb, but if he had had better knowledge of the case he would have started with the intention of removing it. The points he specially desires to emphasize are that this amputation should be adopted as a routine measure in all axillary carcinomas secondary to malignant disease of the breast, and that the subclavicular arteries and veins should be ligated above the clavicle before disarticulation. Then the arm should be cut off and the lymph nodes and other affected tissue removed. A flap from the outer aspect of the arm may be retained to cover the axilla and chest if needed. He also notices cases of this method of operating reported by Mynter and Dent.

51. **Empyema.**—The new method of drainage here suggested is a modification of the ordinary rib resection. The incision is identical with that commonly used; the skin, superficial fascia and muscles divided as before and the ribs exposed; from here on the method differs in that the blunt retractor is not introduced directly into the chest cavity, but is carefully pushed under the rib between it and the pleura, leaving the pleura intact; the rib is excised and in this manner each rib dealt with until the requisite number have been removed. An incision is then made through the parietal pleura parallel with the incision in the skin, the fluid evacuated and a careful survey of the chest cavity made to determine if the lung be adherent to the upper part of the chest cavity. In this case the adhesions can be separated and the lung allowed to expand. The chest cavity is not washed out, which he thinks is not only unnecessary, but dangerous, having in some instances induced fatal syncope. The operation is completed by stitching the pleura to the skin, thus allowing a large and free outlet to the succeeding secretion. In order to avoid injury to the diaphragm, the incision in the pleura should be made from above downward, and the finger introduced into the chest cavity to assure the reaching the lowermost point. It is possible extensive thickening of the pleura and softening may cause difficulty in suturing to the skin, but Brinkman thinks this is hardly likely. There is but one possible objection, which is that occasionally it will be found

necessary to freshen the edges of the wound and approximate the divided surface after suppuration has ceased. In 22 cases done in the above way, the period of convalescence varied from three weeks to five months in the longest period of duration of the purulent discharge. Brinkman summarizes the benefits of the procedure over the ordinary one, in the simpler operation; a large opening, through which the secretion will find exit without the use of tubular drainage, which most commonly is responsible for the continuance of the discharge, no danger that the tube will drop within the chest cavity and be a source of future trouble, and that the period of invalidism is curtailed, thereby minimizing the drain on the system. Inspection of the progress within the chest cavity is possible at all times, and a tendency to the formation of pockets can be eliminated.

52. **Polypoid Growths in Children.**—The object of Adler's article is to call attention to the fact that polypoid growths in children are of much more frequent occurrence than generally believed, and that errors of diagnosis are often made in considering such protrusions, when they occur at the anus, as cases of prolapse. Many cases undergo a spontaneous cure without coming under the surgeon's notice. In size they vary from that of a pea to that of a butternut. Larger ones are occasionally met, but they are exceptional. Intussusception is not an uncommon complication due to the presence of polypi in higher portions of the intestine. A polypus high up in the rectum is generally not attended with any marked symptoms, but when it is low down its presence gives rise to a sensation of fulness and distress in the anal and sacral regions, and bleeding may also be present and of considerable diagnostic importance. The only conditions that could confuse the diagnosis are hemorrhoids and prolapse, and an examination after an enema will usually suffice to clear away all doubts. The only plan to be recommended is removal. It is not safe to cut or tear polypi on account of the possible hemorrhage, and ligature application is not easy. The clamp and cautery may be employed, but the procedure is rather formidable. The ligature may be used, but the simplest method is to grasp the pedicle close to its base with hemostatic forceps and with another pair applied to the balance of the pedicle to gently twist the uppermost one until it comes away. This avoids hemorrhage, pain and long confinement to bed. If the polypus is of considerable size, or if its pedicle is broad and short, a ligature or clamp and cautery should be employed.

61 Professor Adolf Lorenz in St. Louis. F. B. Hall.

54. **The Weight of Infants in Diagnosis and Prognosis.**—Zahorsky figures out the proper growth of infants, giving tables for children artificially and breast fed, and insists on the importance of variations from these scales. In case of loss of weight for one or two weeks, the question of infectious disease should be considered as well as of inefficiency of food supply or disturbance of digestion or metabolism. The quantity and quality of the breast milk must be examined and the condition of the gastrointestinal tract examined, the vomitus, stools, the mouth, and a physical examination of the abdominal organs. The metabolism is studied by urine examination. He calls special attention to the importance of daily weighing the baby for the purpose of adjusting therapeutic measures in infantile disturbances. A continued loss means that our treatment does not succeed, while a corresponding gain speaks favorably. He mentions, however, that a possible error may be due to infantile edema and the loss that necessarily follows change of food. If, in spite of all care, the infant loses in weight and the digestive disturbance is not worse or better, there is good ground for suspecting latent tuberculosis or syphilis.

55. **The Widal Reaction.**—Lademann criticises the technic of the Widal test, claiming that it is by no means a pathognomonic sign of typhoid, but may occur in other conditions, such as sepsis, icterus, etc. He does not denounce the Widal reaction, as it is of some aid if properly done, but denies it has a pathognomonic importance.

56. **Apocynum Cannabinum.**—Paine calls attention to the utility of this drug in Bright's disease and reports a case which was greatly relieved. He thinks we should utilize it in these cases for making life more endurable, though not absolutely a curative agent.

72 Rupture of the Urinary Bladder. John W. Keefe.

62.—See abstract in The Journal, xxxix, p. 854.

65. **Vesical Papilloma.**—Kelly reports a case of removal of malignant papillomatous growth in the interior of the bladder by his operation of incision of the septum, with the patient in the knee-chest posture. He quotes cases as showing the wide applicability of this method on account of the lack of vascularity of the bladder and the direction of the hemorrhage, the thinner wall, the possibility of everting the vesical walls into the vagina and the security of resection and suturing in this way. Lastly, the easy removal of the stitch through the speculum, which makes it possible to use silk or even fine silver-wire ligatures and sutures in the bladder.

69. **Puerperal Eclampsia.**—Abrams sums up the treatment in the word word "elimination," which can be effected, as regards immediate results, in any patient by blood-letting followed by infusion and transfusion of saline solution. If the patient is anemic, do not bleed, but use the saline solution alone. The uterus should be emptied later.

71. **Pelvic Lesions Following Labor.**—Ill discusses the various accidents following labor and calls special attention to the danger of using the forceps before the cervix has become retracted, as more frequently producing serious conditions than many other operative mistakes.

76 Some General Considerations Concerning Diet in Diseases of the Digestive System. Boardman Reed.
77 Amblyopia Due to the Use of the Common Accessories of Diet. Walter L. Pyle.

73. **Diet After Abdominal Operations.**—The importance of the after-treatment of abdominal surgical cases is insisted on by Krusen, who advises the use of one or two teaspoonfuls of hot water only, every fifteen minutes or half hour, after twelve hours, to relieve the thirst, but a still better way is to give a rectal enema of a quart of normal saline solution immediately after the operation. This causes a remarkable alleviation of thirst, as well as the reduction of vesical irritability. Food is usually first administered at the end of forty-eight hours, and may be given by the rectum if the patient is feeble, before that time. The peculiarities of the case and

the tolerance of the stomach must be the guide. The first food should be a teaspoonful of either hot weak tea, beef juice or liquid peptonoids. Milk is a bad food. Good home-made beef tea or any of the numerous concentrated beef jellies may be given in teaspoonful quantities on the second day. Egg albumin is tasteless and nutritious. It is not advisable to give alcoholic stimulants by the mouth, as hypodermics of strychnia and hypodermoclysis of normal saline solution are better. He quotes Penrose, who advises buttermilk as one of the best foods to begin feeding the patient with. It relieves thirst and is more readily digested than milk; one-half to an ounce may be given every hour until the retentive power of the stomach is ascertained. He has found that clam juice or plain clam broth will be retained, and hot oyster soup without the oysters is often acceptable. When rectal nourishment is needed the surface must be cleansed from all mucus and feces and irritation allayed as far as possible. The quantity and quality of the food should be such that it will not excite peristalsis and yet allow of complete absorption. Only such materials should be employed, otherwise they will be irritants. Ewald recommends the following prescription: Beat the whites of two eggs with a tablespoonful of cold water, add a teaspoonful or two of starch boiled in a half teacupful of a 20 per cent. glucose solution. Mix at a temperature below the coagulation point of the albumin. Other things have been advised; meat juice, egg albumin, and peptones, and Senn has cited the use by Kummell of forced nutrition by the subcutaneous injection of sterilized olive oil under the fascia of the thigh in quantities varying from 40 to 60 grams. From the third to seventh day, if the patient is doing well, a soft diet may be given, soft boiled eggs, milk toast, chicken, mutton or beef broth, soups, custards, and jellies and usually after the first week an ordinary diet is allowable.

74. **Diet in Rheumatism.**—Jarvis sums up the diet in rheumatism as a liberal meat diet, cooked by being either broiled or roasted and served rare as being more rapidly digested. Meats should not be boiled until all the salines have been dissolved out of them. Eat carbohydrates in moderation and selected so as to avoid those likely to undergo pathologic fermentation in the digestive tube. Fats in rather small amounts. Water in plenty, and especially some between meals. Alcohol should be prohibited unless it is absolutely impracticable, and only one cup of coffee or tea allowed daily.

75. **The Diet in Contracted Kidney.**—Von Noorden believes in shielding the kidneys from irritation and first of all would exclude alcohol. Unless prescribed, the patient should be instructed that it is a dangerous poison. Most spices should be prohibited, not, however, including salt, vinegar and lemon juice. It is difficult to say just what substances are always harmful, but he would eliminate the following until their non-injurious character is established: White and black pepper, cayenne pepper, paprica, curry, cloves, vanilla (?), nutmeg, English and German mustard, anise, leek, garlic, caraway, knob celery and table celery, asparagus (?), mushrooms (?), morels and truffles. Coffee, tea and tobacco are injurious irritants, though he would not say they should be completely withheld. Restriction should not be delayed, however, until the injurious effects actually appear. The common belief that white meat only should be allowed is objected to by Von Noorden, and he finds it is much easier to get along with a diet selected so as to include dark meats. The allowance of water should be restricted, at least in many cases, as in cardiac disease. According to his experience, it is well to restrict the quantity of fluid to one and one-fourth liters, this to include everything taken in liquid form. This may be difficult in practice and makes special trouble in home treatment. He advises allowing the patient to drink as much water as he chooses one day in the week. If the disease has become incurable, there is no use in aggravating the patient by unduly restricting the diet, but over-feeding is dangerous. The amount should ordinarily be regulated to 4/5 of the calculated normal diet. It is not usually advisable to carry restrictions beyond this point. It is better to prescribe many small meals than a few large ones. As a rule nothing need be eaten between early breakfast and midday dinner but a light lunch, and nothing between dinner and supper but a few mouthfuls late in the afternoon to decrease the appetite for the two chief meals of the day to such an extent that the patient is not in danger of eating too rapidly or of eating too much at one sitting. In more advanced stages of the disease, when the heart is beginning to grow weak, it is best to insist on a light meal every two hours.

81 Fibrosarcoma Cutis. James C. Johnston.
82 The Proposed Dermatological Reform. M. L. Heidingsfeld.

78. **Dermatitis Coccidioides.**—The history of a case, with findings, is fully reported by Montgomery, Ryfkogel and Morrow. The patient suffered from an eruption and enlargement of limbs, with irregular pigmentation, papules, pustules and nodules, involving various parts, the neck, ear and elsewhere, and a superficial elephantiasis with no active inflammation and very little discomfort. The condition broke down into an offensive ulceration with severe pain, fever and rapid respiration, in spite of treatment by the *x*-rays and other methods. The patient finally succumbed. The postmortem revealed a sort of miliary disease of the lungs, resembling tubercles, and extensive areas of broncho-pneumonia. The organism found has a double cycle of growth, one in the tissues and the other in the culture media, which have no features in common, thus differing markedly from blastomycetes. In the tissues it takes the form of a sphere between three and one-half and five microns in diameter, surrounded by a clear, double contoured capsule, the outer wall covered with spines. The smaller capsules have clear or granular contents, the larger one are filled with endogenous spores. Some have a clump of large granules in their center, and frequently they rupture, setting free the granules or spores. The spores are circular, clearly defined, largely refractive and every stage from this sphere to the adult body can be traced. No micropyle has ever been found in the capsule. Frequently when stained with carbol-fuchsin the capsules resist decolorization with acid. Besides the absence of budding, the much larger size of the bodies and their greater number in the tissue distinguish this organism from the blastomyces. In cultures two or three mycelial threads will be seen to spring from a medium-sized capsule, and rapidly branch, and henceforth their life cycle is of the extra-corporeal type, which is that of a mould fungus. In bouillon it appears like fluffy thistledown, and on solid media it is at first white and shiny, and if the media be dry, it sends off aerial hyphæ, forming a fluffy growth particularly well seen on potatoes and carrots. It grows rapidly on all the ordinary media, and liquefies gelatin slowly. It is not anaërobic and does not form gas on any of the sugars. In cultures no coccidial-like bodies are found and no budding forms have been observed. Inoculation experiments proved fatal to guinea-pigs, with lesions of the lungs, peritoneum, kidneys and a general adenopathy without febrile reaction or leucocytosis. The guinea-pigs emaciated rapidly and great numbers of organisms were found in the pus.

79. **Favus.**—Mewborn thinks the same trichophyton produced in different parts of the body two clinically-distinct diseases, favus and ringworm. It appears that the cup-form of favus is due to lack of best suited conditions of the soil. This agrees with the results of experimental study by Bukovsky.

88 *Two Cases of Perforation in Typhoid Fever with Inconclusive Symptoms. James Hendrie Lloyd and Thomas L. Coley.
89 *The Physical Signs and Symptoms of Gastroptosis. Albert P. Francine.

83.—See abstract in THE JOURNAL, February 7, p. 396.

84.—Ibid.

85.—Ibid.

88. **Typhoid Perforation.**—Lloyd and Coley report two cases, in neither of which were the symptoms conclusive or diagnostic, and gave little evidence of the presence of perforations and fecal accumulations in the abdominal cavity. There was pain, but not characteristic, vomiting with more or less abdominal rigidity and later tympanites. He thinks there is need of the careful observation of cases in view of the importance of early diagnosis of perforation of typhoid fever.

89. **Gastroptosis.**—The method of determining dilatation of the stomach, recommended by Francine, is inflation with air through the stomach tube, following lavage, and outlining the stomach by percussion. Special points in the diagnosis are mentioned. Diastasis of the recti muscles should be looked for as an important sign. The blood is usually negative in these cases and the stomach contents usually show subacidity. The urine has been negative, except in the bad cases, where there is excessive elimination of the ethereal sulphates and the presence of oxalates. The presence of a floating tenth rib, considered by Stiller as pathognomonic, seems to Francine to indicate more a special weakness or anomaly in the individual. It is too infrequent to justify much stress being laid on this particular point. The same is true of the splashing sound. The characteristic symptoms of gastroptosis are those of motor insufficiency plus nervous influences. These two react on each other. In so-called primary cases they consist chiefly in distress and flatulence after meals. When general dilatation exists there is apt to be more retention, functional disturbance, gastric pain, nausea, vomiting and some marked autointoxication. There may be palpation of the heart and dyspnea. The pain may be due to associated gastric catarrh or to hyperacidity or to pressure on the solar plexus from the dropping of the stomach. Pain in the back or lumbar region and a sense of dragging of the abdomen are frequent symptoms. Headache, weakness, drowsiness and malaise are often present. Constipation is the rule, though it may be alternated with diarrhea, and diarrhea alone may be present. Nausea on rising may be complained of. Palpitation of the heart, dyspnea and vomiting are not uncommon; anorexia may exist. There is usually some loss of flesh, coated tongue, cold hands and feet, dizziness, numbness of the extremities, etc. There are also various nervous symptoms. The gastroptotic neurasthenic female is a manufacturer of symptoms. Gastric crises, described by Dietl, may consist in attacks of gastric tenderness and pain with slight rise of temperature and transitory jaundice. They have been variously explained as being due to torsion of the pedicle of the kidney, kinking of the duodenum, and recently Stengel has suggested that they may be due to direct pressure of the kidney on the duodenum. The constitutional and neurasthenic picture is very similar to that due to displacements of the uterus, and probably many cases which have fallen into the hands of gynecologists are really suffering from gastroptosis. The author suggests that the two frequently go hand in hand. More attention should be directed to the stomach in these cases; sometimes attention to this point will cause complete relief of all the symptoms.

January.

90 *The Value of an Accurate Knowledge of Arterial Blood Pressure to the Clinician. John Bradford Briggs and Henry Wireman Cook.
91 *Some Observations on the Bacteria of Ice Cream. Henrietta M. Thomas.

90. **Blood-Pressure Estimates.**—The value of an accurate determination of blood pressure in the various diseases is insisted on by Briggs and Cook. While the educated finger is the best assistant in a large proportion of cases it does not quite meet the demands where extreme accuracy is required. The discrepancy between the results obtained by the finger and those of the instruments of precision with the personal equation eliminated, will be surprising to any one who notes it for the first time. The special diseases in which they point out the value of the experiments are in cerebral hemorrhage, nephritis, and especially in obscure comatose conditions where the exact lesion is not readily determinable. The blood pressure may rise in intracranial hemorrhage to a much higher degree than is possible in nephritis, in fact beyond the recognition by the finger, and in the use of drugs which are intended to lower the arterial tension, the occasional use of the Riva-Rocci apparatus may be of great value. In the pseudo form of angina pectoris the knowledge of the actual blood pressure is of great assistance to distinguish it from the true form. Numerous other conditions, such as lead poisoning, gout, and diabetes are also mentioned. They do not wish to be understood as making extravagant claims for a blood pressure instrument nor as denying the value of the educated finger tips. No instrument can ever supplant the "tactus eruditus" but they believe any judgment concerning arterial tension will be a better reflection of actual conditions, if tactile impressions are supplemented by the sphygmomanometer.

92 Report of a Case of Obstruction of the Bowels. L. H. Dunning.
93 *The Uses of Mydriatics. Eugene Davis.
94 Address, Training School for Deaconesses and Nurses at the Deaconess Hospital, Indianapolis. L. H. Dunning.
95 *Intubation of the Larynx, with Personal Reminiscences. F. E. Waxham.
96 *Epithelium and Albuminuria—A Synopsis. Frederick R. Charlton.
97 Tinnitus Aurium. L. C. Cline.
98 *A Century of Arm-to-Arm Vaccination in Mexico. Eduardo Liceaga.

93. **Mydriatics.**—The value of mydriatics in refraction work is specially emphasized by Davis. He thinks in astigmatic cases it is most essential. He has discarded homatropin for this purpose on account of its unreliability and expense, and prefers scopolamin. He prefers the one-grain to the ounce solution, three instillations before refraction.

95. **Intubation.**—Waxham gives his reminiscences of his early work in intubation, introducing it into private practice, which are interesting as illustrating the difficulties and prejudices which he met.

96. **Epithelium and Albuminuria.**—Charlton summarizes as follows:

Just in ratio to destruction of tubular epithelium will albumin be present. Acute parenchymatous nephritis: an active desquamation, but still an acute process, with much of the epithelium maintaining its integrity, hence albumin well marked (0.2-1) but not as high a percentage as in the chronic form. Chronic parenchymatous nephritis; extensive and generalized desquamation, advanced degeneration, lowered resistance, hence larger albumin (0.2-5). Chronic interstitial nephritis: a change in connective tissue with epithelial elements not directly involved, hence little albumin or none. Renal epithelium—the barrier sentinel to the escape of the serum-albumin—the clinical index to albuminuria.

98. **Vaccination.**—This article is a little mixed as to its apparent authorship. It seems to first argue for the efficiency of a single vaccination during life, which is Dr. Liceaga's opinion, as also his endorsement of the humanized vaccine. In the latter part of the article, which is signed by Drs. P. H. Bryce, Wm. H. Welch and Eduardo Liceaga, the history of vaccination is reviewed, and bovine vaccine, especially the glycerinized form, is studied. The principal thing that has been lacking has been the final testing on persons of the quality of each batch of lymph, but this lack must inevitably continue on account of the great demand, absence of a regular supply of persons for experimental purposes and the gradual deterioration of lymph and the necessity of delay in sending it out on account of the possibility of germs. The committee suggests that it would be advisable for the state boards to recommend for use to the local boards only the lymph of such firms as will agree to pay for the presence in their establishment of a trained officer, who could certify that all lymph sent to such state or province has been tested and found to meet all the require-

ments which science to-day demands for the preparation of a lymph of the highest degree of excellence.

The Post-Graduate, New York.

99 *Final Results After the Mechanical Treatment of Pott's Disease. Henry Ling Taylor.
100 *The Microscope as an Aid at Operations. George M. Edebohls.
101 The Use of the X-Rays. James Y. Welborn.
102 The Lorenz Method. Henry L. Taylor.
103 Notes from the Clinics (Laryngeal Growths). Bryan D. Sheedy. Coin in Intestine, Fracture of Clavicle, etc. Inslee H. Berry.

99. **Pott's Disease.**—In 39 cases treated in private practice by the use of the Taylor apparatus where the cases were observed and the results recorded for ten years or more, it was found that:

1. The application of spinal support was nearly always promptly followed by the relief of pain and other acute symptoms, and by improvement in the general health.
2. The disease was cured in 33, and in a considerable number the cure was practically perfect as regards health, figure and function.
3. The result was good as regards deformity in half the cases; 13 cases showed arrest or decrease of deformity.
4. As regards the final amount of deformity, the location of the disease was more important than any other factor, the cervical region being the most favorable, the lumbar next, and the dorsal the least.
5. It was necessary to continue spinal support in most cases long after the pathological cure, owing to the tendency to increase of deformity from static conditions.
6. Ankylosis is therefore later, rarer and less extensive than is usually assumed.

100. **The Microscope in Operations.**—Edebohls remarks on the fact that the use of the microscope was apparently not an adopted procedure in surgical operations in England and France and points out some of the advantages derived from its use, the determination of the character of uterine scrapings, the nature of tumors, etc.

Journal of Eye, Ear and Throat Diseases, Baltimore.

November-December, 1902.

104 *The Treatment of an Infected Corneal Wound with Acetozone. J. F. Klinedinst.

104. **Acetozone.**—Klinedinst reports a case of infected corneal traumatism in which this agent was used with marked success. He has been surprised by the rapid manner in which acetozone controls bacterial infection and thinks that the ophthalmic surgeon has in this agent a germicide which is at once safe and more powerful than any other known. The solution of 1 grain to 2 fluid ounces is strong enough for the eye, though a stronger solution did not seem to do any permanent harm, and only caused greater temporary burning and pain.

107 The Children: How to Examine and What to Look For. George L. Morgan.
108 The Prompt Action of Antidiphtheritic Serum Illustrated in the Histories of Two Cases. J. A. Pipkin.

105. **Appendicitis.**—Mellish advocates the use of Ochsner's treatment by rectal feeding and absolute deprivation of all food by way of the mouth, and elaborates on its advantages. He formerly used small doses of salines in most cases of acute appendicitis, with fair results, and was slow to adopt Ochsner's method in consequence. To show that gangrenous appendicitis can be safely treated in this way he gives a history of a case seen before he left Chicago, and he reports another case in his practice after reaching Texas, which, if operated on at the time, would undoubtedly have proven fatal, but was tided over by the starvation treatment. In order to get the best results from this method, one must have faith in it because it requires courage in the physician to carry it out in every detail. He concludes that treatment by exclusively rectal alimentation is indicated in all cases in which the diseased appendix can not be safely removed by surgical operation. Some points in its favor that are mentioned are that it can be employed by any practitioner under any circumstances, and in case of doubt as to the diagnosis of appendicitis the patient can be safely observed under this method. The conditions most commonly mistaken for appendicitis would be benefited by this treatment. If it is necessary to send a great distance for a competent surgeon, the patient's chances for recovery are not reduced by the necessary delay.

10 Résultats obtenus par l'emploi des composés organométalliques de l'arsenic dans la malaria. A. Gautier.
11 *Les maladies de la demineralisation organique. L'anemie plasmatique. A. Robin.

1. **Transmission of Plague by Fleas.**—Gauthier has been experimenting at Marseilles in regard to the transmission of the plague by fleas. He found that the disease was certainly transmitted from rat to rat by these insects alone. Simple contact or promiscuous intercourse between the rats and infected rats or their cadavers never transmitted the plague in his experiments, while only one out of nine tests with fleas was negative. He also established that the fleas from the rats would bite human beings. The species of fleas found on the land rats was the *Pulex fasciatus*, but another species infested the ship rats, resembling more closely the ordinary flea, that attaches itself to human beings, only possibly a trifle smaller.

2. **Apparatus for Chloroform-Oxygen Narcosis.**—The exact amount of each substance can be gauged and either can be turned off at any moment. The apparatus has a long bag of thin rubber through which the chloroform and oxygen have to pass before reaching the mask. The suction in inspiration alters the shape of the bag so that the respiratory function can be estimated by its changes.

8. **Hygiene of Children.**—This report comprises over 150 pages and reviews all the articles, works and statistics presented to the Académie on this subject during the past year. It includes the report of the children that are charges of the state in its various asylums, etc.

11. **Maladies from Organic Demineralization.**—Robin advocates physiologic instead of chemical therapeutics. Its aim is not like that of the latter to supply what is lacking or neutralize what exists in excess, but it has the higher aim of restraining exaggerated excitability and arousing dormant activities. He proclaims that there is a group of morbid conditions in which one of the factors is a demineralization of the organism or the incapacity of the plasms and tissues to take up and retain the inorganic elements in the food. He recognizes five groups, one including pulmonary phthisis, another phosphorus intoxication, the third a special variety of hemoglobinuria, the fourth various cases of albuminuria which at first merely functional, may terminate in Bright's disease. These include the phosphaturic and dyspeptic albuminurias. The fifth group comprises the anemias, among which certain ones present the clinical aspect of chlorosis. The organic demineralization is evidenced by the increase in the mineral residue of the urine and in the coefficient of demineralization, with corresponding decrease in the proportion of minerals in the blood. Closer analysis will show that this demineralization affects the blood plasm, whose balance in salts is thus upset. The immediate result is either an alteration in the red corpuscles or delay in their renewal or loss of their activity, or all combined. The anemia in such a case might be called "plasmatic anemia," and it can be treated and cured with mathematical precision by restoring the balance of salts to normal. This can be easily accomplished in fifteen to fifty days, as he has proved by his experience. After the balance of the plasm in salts has been restored the red corpuscles soon recuperate under the influence of iron. In a case described gastric insufficiency with hypochlorhydria and secondary acid fermentations succeeding to years of gastric hypersthenia, had entailed profound anemia, which he proved to be of this plasmatic variety. He aroused the dormant glandular and muscular functions by a powder administered five minutes before eating, containing .05 gm. each of potassium sulphate and nitrate, which are stimulants for both the circulation and musculature; .3 gm. of sodium bicarbonate to stimulate the secretion of acid; .01 gm. of pulverized ipecac which acts on the muscular coat and the peripheral nerve center of the stomach, and .25 gm. of pulverized crabs' eyes for a mechanical stimulant. The doses are so small that their action is restricted to the gastric mucosa alone and here they produce a powerful effect. Bread and fermented foods were prohibited and also butter and fats which, by forming a protecting coating over the particles of food, prevent the action of the gastric juice on them. After the meal he administered a mixture of 5 gm. of tincture of ignatia which has a direct stimulating action on the contractility of the muscular coat, and just at the moment when the contents of the stomach require to be stirred up with the gastric juice; with 2 gm. of tincture of ipecac, supplementing this action and stimulating the glands, the mixture completed by 5 gm. of tincture of illicium, which adds its action to the preceding and disguises their bitter taste. Eight drops of this mixture were given in a tablespoonful of a solution of ammonium fluorid in the proportion of .2 gm. to 300 gm. water. This latter drug has the property in minute doses of suspending the activity of the figured ferments while it respects the soluble ferments. It thus checks abnormal fermentations due to the lactic, acetic or butyric ferments, while it does not affect the action of pepsin. In sixteen days the patient had gained five pounds and the stomach treatment was suspended. The remineralization of the organism was then commenced. Robin has been using for four years more or less the following combination for this pur-

pose, every ingredient of which has its definite purpose and efficacy. It contains besides the inorganic salts and iron, both lecithin and albuminoid and ternary substances: Chlorid of sodium, 15 gm.; of potassium, 10 gm.; phosphate of sodium, 13 gm.; of potassium, 6 gm.; glycerophosphate of lime and of magnesia and sulphate of potassium, each 1 gm.; carbonate of iron, .5 gm.; pulverized hemoglobin, 2.5 gm.; glycerophosphate of iron, 15 gm.; yolk of egg, 15 gm.; lactose, 10 gm.; casein, 5 gm.; pulverized ignatia, 1 gm.; and rhubarb powder, 4 gm. It is divided into 100 powders. One is taken before the two principal meals, increasing progressively, according to tolerance, to a maximum of 6 a day.

12. Chemical Sterilization of Water.—Engels has been testing Traube's chlorid of lime and other methods of sterilizing water. The results were far from satisfactory, and he thinks that there is little to be hoped from chemical sterilization except possibly from ozone.

17. Bacteria Growing Through Filters.—Esmarch has had filters examined in thin sections and found that, with the exception of clay (Thon) filters, all were more or less permeated with minute cavities or pores. These pores frequently communicated, and in this way small bacilli were sucked in with the fluid and passed entirely through the filter by capillary attraction.

21. Syphilis and Malaria.—Ruge suggests that possibly the infection in syphilis may be due to a protozoon as in malaria, only in the former disease it requires years instead of weeks to complete its cycle of development.

22. Resistance of the Larvae of Mosquitoes.—The tests reported prove that the larvæ are extraordinarily resistant to cold and mechanical influences.

27. Disinfection of Hands.—Bonhoff announces that the combination of alcohol with formaldehyd and other disinfectants immeasurably enhances the disinfecting power in comparison to aqueous solutions. By far the best results were obtained with an alcoholic 1 to 3 per 1,000 solution of mercury in the form of sublamin.

48. For Cultivating Anaerobics.—Rivas of Nicaragua describes a contrivance which he has found extremely convenient in the cultivation and study of anaërobics. It is merely a flat, rectangular vial, fused at both ends, and so thin that it will slide into the microscope. He has it made with a capacity of 8 c.c.

55 *Die Formalin Behandlung der chron. Endometritis nach Menge. E. Odebrecht.

51. Experimental Pathogenesis of Eclampsia.—Ascoli believes that the side chain theory may yet explain a number of the physiologic and pathologic phenomena of pregnancy. Veit has found that the animal organism reacts to injection of placenta tissue with the production of a cytotoxin or syncytiolysin, which induces albuminuria and may entail hemoglobinemia. Ascoli has been studying these syncytiolysins closer. He used for the purpose a syncytiolytic serum obtained by preliminary treatment of rabbits with placentæ from guinea-pigs. Gravid guinea-pigs were injected with the serum, and contrary to the action of the serum *in vitro* the animals showed no disturbance when the serum was injected under the skin or into the circulation. But when even a small amount of the serum was injected under the dura the animals sank into profound coma, interrupted with tetanic, clonic and tonic spasms, affecting parts or the whole of the body and terminating in death, without delivery, in progressive coma. Reduction of the amount produced the same picture, but much less intense and the animals finally recovered. Ascoli expressly states that he experimented with such numbers of animals and with sera from so many sources that the facts announced are absolutely established beyond question. Similar injections of normal serum were borne without any reaction and after the prepared serum was heated to 60 C. its effect was remarkably attenuated. On the other hand, rabbits treated with this serum showed no disturbance, showing that it is strictly specific for guinea-pigs. The testimony thus offered by Ascoli's experiments, that the syncytiotoxins elaborated in the organism after introduction of placenta tissue are capable of inducing a clinical syndrome resembling eclampsia when injected into other gravid animals, suggests that the deportation of placenta cells swept away by the maternal blood current may have a share in the production of eclampsia. If this assumption prove to be correct it would explain the predominance of eclampsia in primiparæ, as a certain immunity may be acquired in time. The evil effects of the toxin may be felt principally in the nervous system or in the kidneys, or both may be affected at the same time, as manifested by the coincidence of albuminuria with the eclampsia. The tardy appearance of eclampsia postpartum might be explained by the length of time required for the organism to form such antibodies, as a certain period of incubation may be assumed.

55. Formalin in Chronic Endometritis.—Odebrecht has been using formalin for local applications in the uterus on an

extensive scale, according to Menge's suggestions (*Arch. f. Gyn.*, lxiii, 1). His experience has been remarkably favorable, and he thinks that much less harm is liable to result from its use than from other local measures. He extols its efficacy in the treatment of fluor, hemorrhages and pains and the benefit to the general health as local lesions subside. An interval of a week is usually necessary; four to ten days is his range, and his maximum has been eight to ten applications of a 50 per cent. solution. He applies it on cotton with a Playfair sound. Decidual and hemorrhagic endometritis require curettement, but with these exceptions the formalin will be found the best treatment known to date and it does not conflict with curettement or other measures later if deemed necessary.

64 Fall von epidermoidaler Metaplasie der Harnwege (urinary passages). F. Stockmann.
65 Urologische Casuistik. M. Kreps.
66 (No. 12.) *Ueber die Ausscheidung (elimination) der in die arterielle Blut-Bahn injizierten Bakterien durch die Niere. P. Asch.

56. **Idiopathic Inflammation of Cavum Retzii.**—Hassler thinks that cases published under this heading have been in reality consecutive to some latent affection of the urogenital system, probably gonorrheal. He does not believe that there can be an idiopathic inflammation, but occasionally a submuscular hematoma may be the source of the irritation. The hematoma may occur as the result of trauma or severe coughing or from degeneration of the wall of some vessel.

57. **Sterilization of Catheters.**—Goldberg infected the catheters by submerging them for one to several hours in purulent urine. Sterilization afterward was always readily and most easily accomplished by boiling the catheters in water for five to ten minutes in a vessel longer than the instruments. He advises cleaning them mechanically with hot soapy water immediately after using. A current of steam at 100 C. is also an effective means of sterilization, but fluid antiseptics are entirely unreliable.

59. **Endophotography of Urethra.**—Cohn gives several photographs of the views obtained through the urethroscope. Those obtained with the Nitze-Oberland urethroscope were superior to the others.

66. **Elimination of Bacteria Through the Kidneys.**—Asch injected the colon bacillus and the lactis aerogenes into the arterial circulation of animals. They were never eliminated through the kidney as long as it was sound. If the bacilli were discovered in the urine some affection of the uropoietic system was always present.

67. **Food Required by Diabetics.**—The results obtained by tests of diabetic patients at Nothnagel's clinic are given in tabulated form for each group of patients, classed according to the predominance of certain symptoms. Schlesinger mentions that in several cases the moment the last trace of sugar vanished from the urine the weight suddenly increased out of all proportion to the amount of food ingested. He suggests that possibly the sugar draws the water out of the tissues and as soon as the proportion of sugar is reduced to normal, the tissues take up water with avidity, which simulates an increase in weight. He has noticed that the tissues of diabetic cadavers are always remarkably dry. But even accepting this assumption the abrupt increase is still incomprehensible.

68. **Influence of Light on Motor Apparatus and Reflex Excitability.**—In experiments on sixty frogs Büdingen was unable to detect the slightest indication of any action of blue and red arc light or sunlight on the nerves or muscles or the reflex excitability, nor on respiration or metabolism. He adds that the only influence of light thus far established is that on the eye, on the spirits and on the skin, and on a few micro-organisms pathogenic for man. Quincke has also established an increased oxidation in pus cells, leukemic blood and ground human organs, but no proof has yet been offered that these oxidations occur in the same way in the living body under the influence of light.

69. **Indications for Mineral Mud Treatment.**—In Mory's experience the results of this treatment have been brilliant in chronic rheumatic affections of the joints and also in acute or chronic attacks of gout. Even in the midst of a typical acute attack when the slightest contact caused excruciating pain, the application of several pounds of fango relieved the pain at once. The foot did not feel any contact but felt as if suspended in air and softly touched with velvet. Old gouty subjects who have spent a small fortune on piperazin, etc., are the most enthusiastic in its praise. He applies it at 55 C. The fango is also indicated in lumbago and cures every case of sciatica uncomplicated by caries of spine or pelvic tumors. It is also effectual in neuralgia elsewhere, even in head and face. The fango from Battaglia is a volcanic heat product from the bowels of the earth and has never come in contact with the earth's surface. It is liable to give excellent results in gynecologic affections, metritis, oöphoritis and salpingitis. In one case a patient had been confined to bed for eight months on account of a febrile gonococcus adnexitis. The surgeon declined to operate owing to the multiplicity of suppurating foci. After three weeks of fango treatment she was able to get up. Two months later there was recurrence of some of the symptoms which were definitely banished by six more fango packs. He sometimes supplements local application in such cases by filling the vagina also with the fango. In gallstone colic he has frequently witnessed the relaxation of the duct and expulsion of the stone after ten minutes' application of the fango. The pains from sprains and fractures are likewise amenable to fango treatment.

73. **Treatment of Enuresis.**—Walko has cured 10 cases of idiopathic and 3 of symptomatic enuresis. In one case of tabes the enuresis was unaffected by his measures, but a second similar case was cured. In one case the enuresis was a symptom of slight cystitis and subsided under treatment of the latter. Combined massage through the rectum succeeded in three to five applications, the patient in the knee-elbow position or on his back. One hand applied above the symphysis presses against the hand in the rectum, followed by light massage of neck of the bladder. In one case the enuresis of twelve years' duration was cured by hypnosis in a single sitting. He is convinced that in many cases the cause of the enuresis is an inhibiting phenomenon of a psychic order occurring in a normally-developed organ. The circumstance that enuresis lasting from early childhood and past puberty could be completely cured in this way, as occurred several times in his experience, demonstrates that there can be no question of an anomaly in development or of weakness in the musculature.

77. **Action of Sweats.**—Krebs proclaims that the benefit of therapeutic sweats does not lie in any qualitative or quantitative alteration in the blood. It is due rather to its influence on the tissues by the modification induced in the conditions of the circulation.

78. **Value of Daily Weighing in Heart and Liver Affections.**—Jacobäus states that it is possible to determine whether more dropsical effusions, ascites, etc., are accumulating or whether the fluid is being eliminated, if the patient is weighed every day as a routine procedure. Abnormal retention of water may be detected by this means long before any clinical signs of dropsy are apparent. Daily weighing showing gain or loss is an important guide for the continuance of carbonated baths or other measures and also for the diet. The patient need not be restricted in drinking if the daily weighing is satisfactory. The aim in treating a chronically-diseased organ is to train the sound organs to supplement or substitute it and the value of the skin in this respect in heart disease must not be overlooked. Here again the progress gained can be estimated by daily weighing.

79. **Peat Baths in Heart Disease.**—Loebel has found peat baths useful in neuroses and arteriosclerosis of the heart, especially in cases of fatty degeneration, with high blood pressure. Dropsical disturbances in compensation are beyond their reach and they are contraindicated in this condition on account of the low blood pressure. He never orders the baths with a blood pressure of 130 mm. or under, as he has known of too many instances of the heart giving out under these circumstances. The peat baths require even greater vigilance than the carbonated baths in this respect.

83. **Superheated Air Therapy.**—Grünbaum points out that higher temperatures can be attained with hot air than with any of the other local applications of heat. With water the highest limit that can be reached without burning the tissues is 40-50 C.; with peat or fango, 45-55 C.; with steam, 50-60 C.; with sand, 55-65, but superheated air can be borne at a temperature of 80-90 C., equivalent to 194 F.

85. **Dietetic Abortion of a Cold.**—Sternberg has revived a method of aborting a cold promulgated by Williams in 1841. He has found it effectual on himself and others and recommends it as a simple and easy method of curing coryza. It consists merely in refraining from the ingestion of any fluid for twenty-four hours after onset of the cold and for twenty-four additional hours after the coryza develops. The natural fluid secretions are not curtailed by this abrupt cessation of all intake of fluid, but the cells do not have enough moisture to generate the abnormal catarrhal secretions. Consequently the irritation of the tissues by the catarrhal secretions is eliminated, and the tissues rapidly recover their normal tone. The morbid membrane, no longer irritated by its own secretion, speedily resumes its normal condition instead of the perpetuation of the vicious circle as in the ordinary coryza. Thirty-six hours are frequently long enough to completely abort the cold. It is not followed by a cough and expectoration. Chronic nephritis is the only contraindication to this water starvation of a cold.

87. **Range of Temperature in Tuberculous Sanatorium Patients.**—Kuthy makes a point of studying the fluctuations of the temperature in all tuberculous patients, even in the afebrile. The lesser the range the better the prognosis, he thinks, and aims to reduce it to a fraction of even the normal range. When this can be accomplished it shows that the diseased organism, while taking in and putting on all aids to its defense, is also becoming saving of its outgo, thus making less demands on its chemical energy.

96 Ueber die sog. Carunkeln der weiblichen (female) Urethra. M. Lange.

90. **Primary Cause of Tubal Pregnancy.**—Opitz found traces of old salpingitis in the tubes involved in 23 cases of tubal pregnancy. Trivial adhesions and folds, the relics of the old inflammatory process, had evidently favored the retention of the ovum in the tube. His findings impel him to emphasize that all tubal pregnancies should be regarded as malignant tumors and treated accordingly.

91. **Pregnancy and Childbirth After Rupture of Uterus.**—Stroganoff sutured the rupture in the case he describes by celiotomy. The patient was a v-para and the rent extended from 3 or 4 cm. inside the left round ligament to beneath the right ligament. The woman returned later at term with a normal pregnancy, which proceeded to a normal termination. The only intervention necessary was version and extraction owing to the non-elasticity of the cervix from the cicatricial tissue. He remarks that women conceiving after a rupture of the uterus should be placed in a favorable environment during the last two or three months of gestation, with oversight and preparations for prompt operative aid at need. He has since had occasion to observe a second somewhat similar case. The patient was a vii-para and laparotomy was necessary as the fetus had escaped into the abdominal cavity. The rupture extended from the front, left lower third of the cervix upward to the attachment of the right round ligament. The left round ligament was also involved in the rupture. The following pregnancy was normal, but as in the first case the fetus did not present at the inlet to the pelvis owing to the rigidity of the cicatricial tissue in the cervix. The patient was artificially delivered with bougies dipped in glycerin. The head presentation was changed to a breech by external manipulations. The uterus is liable to rupture a second time so that everything must be ready for a laparotomy. After delivery the site of the rupture should be inspected. In a case reported by Kriwsky the rupture was not complete and consequently was not sutured. The uterus ruptured again at the close of the following pregnancy, requiring supravaginal amputation.

92. **Opitz's Sign of Abortion.**—Some time ago Opitz announced that in 140 scrapings of the uterus in 40 cases of preceding abortion he had found striking alterations in the glands which he assumed to be evidence of the preceding abortion and of a pregnancy of at least eight weeks' duration. Seitz now reports that he has discovered the same alterations in four characteristic cases of endometritis in which the assumption of a preceding gestation or abortion is absolutely out of the question. He accepts them as evidences of endometritis glandularis hypertrophica. In one patient an old bilateral gonorrheal adnexitis rendered conception improbable. In the others menstruation had been regular and profuse to the day of operation.

94. **Study of Twins.**—Weinberg presents statistics of twins with one and with two ova, and discusses the origin of sex.

97. **Appendicitis in Pregnant Women.**—Twelve cases of appendicitis occurring during the course of pregnancy or in the puerperium are described in detail. In 4 of the 9 cases in pregnant women, the pregnancy continued without interruption to term, although the appendicular abscess was evacuated in 2 of these a few weeks before delivery. In 4 premature delivery or abortion occurred before death. The patients were in the first, fourth, eighth or ninth month. Five of the 9 pregnant women died, and one of the 3 in the puerperium. Only 2 died out of the 6 operated on for generalized peritonitis. The benefits of prompt operation were so apparent that Rostovtzeff urges as a principle that surgical intervention should be exceptionally prompt in case of appendicitis occurring in a pregnant woman. In the majority of cases the pregnancy will not be interfered with, and in case abortion does occur, the consequences will not be so serious as in the unoperated cases. He unconditionally discountenances artificial delivery on account of appendicitis, which has been recommended by some writers.

99. **Calomel Injections in Elephantiasis.**—Two Russian physicians have reported excellent results from calomel, and Tiptzeff now describes another case in which the improvement was marked after intramuscular injections of .05 gm. calomel in vaselin oil every second to fourth day, for three and a half months. He thus injected a total of .7 gm. calomel in fourteen injections. The patient was a woman of 39 and her legs were gradually reduced in size by .5 to 2.5 cm. and in certain portions by 3 to 7.5 cm., and appeared comparatively normal. She was a syphilitic, but the syphilis had been acquired after the development of the elephantiasis. [Tchlenoff also reports in No. 11 a case of elephantiasis in a syphilitic notably improved by subcutaneous injections of calomel. Another Russian has since published the cure in a month of an old, rebellious leg ulcer in a woman of 61, treated by a subcutaneous injection of .05 gm. of calomel once a week, supplemented by a compressing bandage. He also noted that lupus patches healed very rapidly after curetting if calomel were injected.—Ed.]

100. **Phosphorus in Alopecia.**—Byalobzhesky treats alopecia on the assumption that it is a nervous affection, administering phosphorus in small doses. There is no further falling out of the hair, and the bald patches gradually grow over, commencing at the periphery. His formula is .06 gm. of phosphorus dissolved in olive oil and mixed with .1 gm. of arsenic acid and some vehicle to make 120 pills. One to four are taken every day for two to four months with intermissions of a week, until two or three hundred of the pills have been taken.

101. **Formalin in Cutaneous Affections.**—The preparation of formalin, tannoform, is proving remarkably effective in the treatment of intertrigo, especially for children. Also for hyperidrosis of feet and axillæ. In Velyamovitch's experience a 25 per cent. solution of formalin is still more effectual for the feet, and a very weak solution for the axillæ, not more than 5 to 7 drops of formalin in half a glass of water. In the sweats of pulmonary tuberculosis he uses a still weaker dilution. He recommends undiluted formalin for cauterizing dirty, infected wounds or ulcers, and makes a practice of soaking the field before operations with a compress impregnated with a .5 to 1 per cent. solution of formalin applied for fifteen to twenty minutes, as a preliminary to surgical intervention.

103. **Cure of Local Tuberculosis.**—After fifteen years of experience and observation of hundreds of cases, Serenin proclaims as a fundamental principle in the treatment of local tuberculosis that such patients should not stay in hospitals a day longer than is absolutely necessary. If an operation is required it should be done as promptly as possible, and then the patient should at once be given the benefit of country air, although kept under medical surveillance. Recovery proceeds more rapidly in exact proportion to the level of the general health. He also states that surgical intervention should aim to remove all the diseased parts into sound tissue, but if this is impracticable, the wound should not be closed, but merely tamponed with gauze.

105. **Trophoneuroses of Extremities.**—Michailoff gives 5 illustrations and descriptions of 11 cases of trophoneurosis, angioneurotic disturbances or angiosclerotic gangrene.

106. **Local Injections of Carbolic Acid in Scarlet Fever.**—Polievtkoff gives a cut of a mouth gag and Pravaz syringe with a long needle bent in an obtuse angle to the body of the syringe. He injects with the aid of these instruments a 3 per cent. solution of carbolic acid directly into the tonsils or soft palate in case of scarlet fever and has found the procedure simple and effective in curing the angina and preventing diphtheria. He has thus treated 110 hospital patients, and his mortality has been 16 per cent. The best results are attained when the injections are commenced the second day of the disease. He keeps them up for four or five days, or until the fever subsides, but in the severer cases for seven to eight, with close watch over the urine for symptoms of intoxication. Heubner in such cases repeats the injections twice or three times a day, but Polievtkoff makes only one injection on each side once a day, graduating the dose to the age. The syringe holds 3 gm. and one-third is used for one injection in children under 6, and two-thirds for older children at each injection. He tabulates the exact results obtained.

108 and 109. **Prophylaxis of Extragenital Syphilis.**—Roche reports a case in which a young woman of good family contracted syphilis from a kiss on her neck by her fiancé, who was found to have a syphilitic lesion in the mouth alone, undoubtedly due to his having smoked a cigar taken from the mouth of a syphilitic friend. Pawlow describes the experience with syphilis in the Moscow department of the army, and states that the largest majority of cases had more or less discharge from their lesions, rendering the subjects possible sources of contagion. In fact extragenital infection was contracted in this way by 29 soldiers, notwithstanding the strict prophylactic measures enforced and the efforts made to educate the populace in regard to the dangers of venereal diseases. He suggests that syphilitic soldiers should be detailed to special companies from which the non-syphilitic should be weeded out.

110. **Value of Suprarenal Extract.**—Ivanoff lauds suprarenal extract as a harmless and vigorous vasoconstrictor, destined to the widest application in hemorrhages of internal organs and also in the treatment of acute and chronic inflammations of the mucous membranes, describing his experience.

112. **Kidneys in Croupous Pneumonia.**—Abramoff describes 6 cases of croupous pneumonia in which there were evidences of acute glomerulonephritis. The patients were between the ages of 22 and 52. The involvement of the kidneys was manifestly the cause of death in these cases, while in 6 other cases of croupous pneumonia observed during the same

year, death was due to fatty degeneration of the heart muscle in 3, and to suppurative meningitis, chronic endocarditis or excessive hypertrophy of the heart in one each.

113. **Laparatomy on Pregnant Women.**—Warnek states that all of his 17 patients operated on during pregnancy recovered. Abortion occurred in 3 out of the total 17, while 2 were delivered at the eighth month and 6 continued to term. The ultimate outcome is not known in 6 others, but the pregnancy continued undisturbed when last seen. In 10 of the patients the ovary was removed on account of a cyst or dermoid tumor, and with one exception all the patients were presumably delivered at term afterward. This exception was a case of dermoid tumors in both ovaries. In one of the patients part of the tube was removed with the ovary, and in another two-thirds of the second ovary. The recovery from the laparotomy proceeded normally in every instance. In 2 the patient was delivered at the eighth month, that is, four or five months after the intervention, which in all probability had nothing to do with the premature birth. In one patient, ten days after removal of the ovary and part of the tube, an adenoma of the breast was extirpated. The patient was in the sixth month of pregnancy. It continued to term, but there was considerable hemorrhage with delivery and fever for six weeks. The patient became pregnant again in four and one-half months afterward. His eleventh patient was relieved of the products of a four-months', ruptured, tubal pregnancy, without interfering with a six months' normal pregnancy, which continued to a normal termination with the delivery of a healthy child, the mother in her thirty-fifth year. Cases 12 and 13 demonstrate that surgical intervention is possible on the uterus itself without interference with the pregnancy. In these cases a submucous fibroma or myoma located in the fundus was removed without disturbing the three and five months' pregnancy. In case 14 the diagnosis wavered between an ectopic pregnancy, adnexitis or abnormal uterine pregnancy. Conditions were found normal at the laparotomy except that the uterine walls were extremely flabby. The abdomen was sutured, and three days later a macerated fetus was expelled. The uterus required curetting a week later, after which the patient rapidly recovered. No temperature after either operation; wound healed by first intention. In 2 other cases the laparotomy revealed adhesions which prevented the normal development of the pregnant uterus. After their removal gestation proceeded to an uninterrupted termination. The last case was one of umbilical hernia, which required a plastic operation. The pregnancy continued undisturbed. The age ranged from 18 to 40, and the patients had nearly all borne one to several children before.

115. **Superheated Air in Rhinolaryngology.**—In 40 patients with various affections of the throat and nose, 25 were cured, 2 improved, and no results could be determined in 13, all treated by the application of superheated air. It proved most effective in cases of acute and subacute coryza, swelling and hypertrophy in the throat, gumma breaking down, in ozena and in neuroses. It did not prove effectual in atrophic processes nor in case of hypertrophy of the nasal passages.

116. **Emigration of Pus from Abscesses in Liver.**—Mejia's article is illustrated and shows that exact knowledge of the location of the pus and of its bacteriology are of the utmost importance in treatment. The pus generally makes its way toward the bronchi and right lung, but it may make irruption into any of the thoracic or abdominal organs. Intervention should always be preceded by puncture, which is perfectly harmless in the liver if the needle is not twisted from side to side. This is liable to cause hemorrhage. When the abscess in the liver protrudes in the epigastrium the incision should be made as close to the ribs as possible in order not to interfere with healing by retraction of the liver. He calls the region including the three lower interspaces on the side of the trunk the "teritorio hepatico," and states that all intervention directly on the liver should be in this region. It embraces the interspace above and follows the costal arch below.

119. **Prognosis of Mexican Typhus.**—Sweats are not a favorable sign unless they coincide with improvement in other symptoms. As a general rule Terres thinks that it is almost impossible to draw an accurate prognosis, especially in apparently mild cases. He states that the deaths from this cause in Mexico were 6, 896 in 25, 327 cases recorded between 1893 and 1901, a mortality of 27.22 per cent. The mortality in the Juarez Hospital was 26.56 per cent. In the discussion that followed his address several speakers mentioned that the disease was much less serious among the illiterate. The wealthy and medical students seem to succumb to it in greater numbers. This may possibly be due to their fear of the disease. Mendizabal remarked that possibly excessive care and medication were responsible for the greater mortality among the well-to-do. They died from "typhus complicated by physician." All concurred in accepting that intellectual work and chronic alcoholism materially affect the prognosis in an unfavorable manner.

121. **Mosquitoes in Transmission of Disease.**—Orvananos notes the coincidence of the occurrence of epidemic typhus in Mexico with innumerable mosquitoes in the quarters attacked. He believes that malignant carbuncle and other diseases are propagated by the mosquitoes, as he has watched the insects at night flying around the rooms and "palpating" every exposed surface. When a colored powder was scattered lightly over certain exposed surfaces the proboscis of more than half of the mosquitoes could be seen stained with the powder next day.

125. **Puerperal Septicemia.**—In 59 cases of this affection observed by Hermosa he noticed that the cervix was open and the muscular fibers of the lower segment of the uterus were relaxed from the very beginning of the infection. In other cases of febrile accidents during the puerperium, the cervix was not dilated and experience proved that the infection in these cases was not in the uterus. When the cervix was found closed the infection invariably proved to be due to some intestinal or other trouble and the uterus was disregarded in treatment. In case of grave uterine infection he administered large doses of quinin and strychnin, for their antithermic, antiparasitic, tonic and oxytocic action, with a milk diet and subcutaneous injections of large amounts of artificial serum, slightly iodized. He has lost only one out of his total of 59 cases thus treated, none in his private practice.

137 A Case of Hernia into the Fossa Duodeno-jejunalis. Charles T. Andrew.

130. **Tumors of the Bladder.**—Freyer describes the different forms. Papilloma is the most common, usually single and varying from the villous form—like a swab—to the mere substantial sessile or the pedunculated growths. The latter may

occasionally become detached. Cystitis is not an infrequent sequel of these tumors. One type of tumor consists of short thickset papillæ, more dense in composition, which he calls fibro-papillomata. The presence of villi is not an indication of non-malignancy. The size of the papilloma may vary from that of a pea to an orange and the growth may be either rapid or slow. He mentions a case where it undoubtedly existed for eighteen years. Between the benign papilloma and the malignant, there is a type he calls the transitory, which has a tendency to recur, after removal, become more and more fleshy, with infiltration of the surrounding mucous membrane and the patient ultimately dies of true cancer. Adenomata are rare if they ever occur. Epithelioma is next to papilloma in frequency of occurrence and is very rare before the age of 40. It may commence as a warty outgrowth, a simple fissure or an irregular ulcer, but rapidly advances. It may in the later stages ulcerate into the bowel or may appear in the groin or make its way through the sacro-sciatic foramen and involve the sacral nerves. Connective tissue tumors are rare. Fibromas must not be confounded with fibro-papilloma, which has its origin in the mucosa while the fibromas spring from the fibrous tissue in the muscle coat and are rarely pedunculated, and almost invariably found in adults. Myxomas usually occur in young children and are generally multiple. Myomata are extremely rare; they arise in the muscle coat and may project inward or outward. Sarcoma is the most common of the connective tissue tumors, but it is rare in comparison with epithelial growths. It may occur at any age as a dense rapidly-growing tumor involving the entire thickness of the bladder wall. The round- and spindle-celled varieties are those most frequently found. The symptoms are noted, such as hematuria, increased frequency of micturition, pain, urinary retention and pus in the later stage after cystitis has developed. The cystoscope is described and the technic of operations for bladder tumors. When a malignant growth is confined to the apex of the bladder where section may be performed extraperitoneally by stripping off the peritoneum over an extensive area, Freyer considers operation not only justifiable, but advisable. When the base of the bladder is involved he considers any attempt at resection futile.

131. **Reflex Convulsions in Growing Boys and Girls.**—Smith questions the diagnosis of epilepsy frequently made in the case of convulsions of children after infancy and points out that such convulsions very often co-exist with digestive disorders or some other local irritation and cease when the local condition is removed. Many cases also of hysterical attacks in young unmarried women are, he considers, of such a nature. He reports a number of cases and calls attention to the certain fact that the impressionable nervous system may be permanently affected if the irritation is long continued. One common symptom in all instances quoted was that of habitual cold feet, which he remarks as indicating a condition which may thwart our best efforts to treat a chronic complaint of children, indirectly affects the nutrition, heightens the sensibility to chills and thus any weakness or injurious tendency is aggravated. In some cases the attacks recur in spite of treatment. It is probable that they are then not true cases of reflex convulsion, even at the beginning, but as a rule the intellect does not seem to be affected. Such cases are exceptional. In the majority of instances where the fit occurs in a child who is the subject of temporary digestive upset, we may reasonably expect complete cessation of symptoms and permanent restoration of health by proper treatment. Many observed cases warrant him in saying that young persons who have been subject to such seizures as late as 12 years old, may grow up into perfect adults without showing any later symptoms of the weakness of their childhood.

132. **Sea-Borne Plague.**—Freer gives his experience as a ship surgeon and criticises the way in which the directions of the Venice convention have been carried out. He thinks it is almost impossible to clear a ship of rats by any method of disinfection. Passenger ships are worse than freighters in this respect. The disinfection of clothing and crews is very imperfect. Owing to the precautions taken where surgeons are employed, it is most unlikely that any person infected with plague can board a ship at an infected port and in the majority of cases the ships are infected on board either by rats, clothing, bedding or cargo. He thinks the time has come for the recommendations of the Venice convention to be reviewed and modified. He is of the opinion that no native sailor should be allowed to bring any clothing or effects from his home on board the ship, even if disinfected. The isolation of the ship from shore rats is very defective. The funnels which are placed on lines connecting the ship with the shore are often very little protection, and the rats go up and down the gangplanks, often unmolested. He also believes there should be some continuity of action and uniformity in methods for granting pratique to vessels in different ports. A scheme should be devised by an international commission that would be fundamentally the same at all ports.

133. **Sulphuretted Hydrogen Poisoning.**—Oliver reports several cases occurring in a caisson in building a dry-dock and remarks on the dangers of alkali waste, slag, etc. It is difficult to tell just how sulphuretted hydrogen kills. He has not found the hemoglobin in the blood altered in any way in the cases examined, neither the men who succumbed to the gas nor the dog subjected to the gas experimentally. He remarks that excavations close to slag heaps or the waste of chemical works should be conducted with the greatest caution. It is dangerous to allow buildings, especially for living purposes, to be erected close to either slag or chemical waste products. The odor of sulphuretted hydrogen should be regarded at once as a danger signal. Before allowing men to work in confined spaces where there is a suspicion of sulphuretted hydrogen, the plan might be adopted of exposing a piece of filter paper soaked in lead or silver solution. A cylinder of oxygen should be at hand, together with other measures for reviving those who may be overcome.

134. **Rheumatic Fever.**—O'Conor reports cases of his method of opening the joint in cases of rheumatic fever. He says:

> While advocating early surgical interference in rheumatic fever I can not too strongly deprecate any attempt at the same without the operator feeling assured that he commands all the ordinary essential elements with which to carry out an ordinary aseptic operation. It is obvious that under septic conditions this method of cure might readily be attended with greater disasters than might even originate from the disease itself. To any one about to put my practice to the test may I suggest: (1) do not puncture, open knee-joints; (2) ligate all bleeding points; (3) drain, do not cork.
>
> Also, I wish to insist on the great value of thorough drainage in these cases, for it would be a more imbecile act to close a joint containing such toxemic stuff than to seal hermetically a recent ischio-rectal abscess cavity. In order to carry this properly into effect in operations on the knee-joint an incision an inch long is made on each side of the joint through the capsule. Through both openings a long closed forceps is passed and a fenestrated india-rubber tube, half an inch in diameter, is drawn across the synovial pouch, leaving about half an inch of tubing presenting at each wound. Drainage having been thus secured the joint is washed out every morning with a jugful of warm carbolic lotion (1 in 60) and the tube is generally dispensed with on the third or fourth day. Irrigation of the joint is daily continued until healing no longer permits of the passage of fluid.
>
> A little superficial necrosis of wound tissue caused by pressure of the drainage tube need not excite alarm, as this rapidly disappears under an iodoform gauze dressing. The latter, by the way, is made fresh for each dressing by immersing pieces of dry sterilized gauze in a solution of equal parts by weight of iodoform, alcohol and glycerin. A little formalin (1 in 500) is added to the mixture before use. In arthrotomy of the wrist and ankle-joints drainage is attained by a piece of gauze passed into the joint through the open blades of a dressing forceps previously inserted.

138 *Surgical Tuberculosis in Egypt. Frank C. Madden.
139 Case of Double Continued Fever. V. Gunson Thorpe.
140 Remarks on the Individuality of "Filaria Diurna." (Continued.) Louis W. Sambon.

138. **Surgical Tuberculosis in Egypt.**—According to Madden, the surgical forms of tuberculosis are remarkably frequent in Egypt. They are rarely associated with medical tuberculosis, such as phthisis, meningitis and intestinal lesions. While the majority of cases occur in the young, the average age is higher than in England. They can fill every ward over and

over again, he says, with patients suffering from surgical tuberculosis, waiting for admission. Lupus vulgaris is very common and though sunlight is excellent, the Finsen method is so slow and tedious that it would be hard to make it practical. Tubercular cervical glands are extremely frequent also, sometimes enormous. Bone tuberculosis is also common. In 30 cases recently seen there were 4 of tuberculosis of the sternum, which is a much more frequent affection in Egypt than in England, and tubercular dactylitis is also very common. Another form is that affecting the posterior surface of the lower end of the femur. Spinal caries is not frequent, but there are many cases of tuberculosis of the pelvic girdle. Tubercular joints are also rather frequent; that of the knee is fairly common and also of the ankle. Tubercular shoulder is rather rare, but tuberculosis of the wrist, elbows and ankles almost always requires amputation, and also tubercular knee joints, as they are so advanced when seen. He also mentions tuberculosis of the epididymis and testis, but has never seen a case of tuberculosis of the kidney or bladder. Primary tuberculosis of the peritoneum is fairly frequent. If only the lower class of natives can be educated to observe the ordinary rules of cleanliness, and of the head in particular, good results might be expected, but the difficulties are very great. It is certain that if something is not soon done, tuberculosis must come to be numbered among the modern plagues of Egypt, in the same category with syphilis.

Books Received.

Acknowledgment of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review, as dictated by their merits, or in the interests of our readers.

HUNTINGTON'S ABDOMINAL ANATOMY. The Anatomy of the Human Peritoneum and Abdominal Cavity Considered from the Standpoint of Development and Comparative Anatomy. By George S. Huntington, M.D., Professor of Anatomy in the College of Physicians and Surgeons, Columbia University, New York City. 590 Pages, Including 300 Full-page Plates in Colors and Monochrome. De Luxe Edition. Price, $10.00 net. Philadelphia and New York: Lea Brothers & Co. 1903.

QUIZ COMPENDS. A COMPEND OF DISEASES OF CHILDREN, Especially Adapted for the Use of Medical Students. By Marcus P. Hatfield, A.M., M.D., Emeritus Professor of Diseases of Children, N. W. U. Medical School. Third Edition, Thoroughly Revised, with a Colored Plate. Cloth. Pp. 241. Price, $0.80 net. Philadelphia: P. Blakiston's Son & Co. 1903.

AN EPITOME OF PHYSIOLOGY for Students and Practitioners of Medicine. By Theodore C. Guenther, M.D., of the Norwegian Hospital, Brooklyn, and Augustus E. Guenther, B.S., Formerly Assistant in Physiology in the University of Michigan, Ann Arbor. Cloth. Pp. 250. With 57 Engravings. Price, $1.00 net. Philadelphia and New York: Lea Brothers & Co. 1903.

ANNUAL REPORT OF THE DEPARTMENT OF HEALTH, City of Niagara Falls, N. Y. For the Year 1902. Submitted by Carl G. Leo-Wolf, M.D., Health Officer. Paper. Pp. 61. Niagara Falls, N. Y.: The Gazette Press.

The Public Service.

Navy Changes.

Changes in the Medical Corps of the Navy, for the week ended January 31:

P. A. Surgeon J. C. Rosenbleuth, resignation accepted, to take effect Jan. 23, 1903.

Medical Director G. F. Winslow, retired from active service on his own application, after forty years' service.

Medical Director J. A. Hawke, retired from active service, having reached the age of 62 years.

Drs. H. L. Brown, T. C. Blackburn, P. L. Cocke, G. F. Duncan, V. Dabney, J. B. Mears, P. S. Rossiter and P. F. McMurdo, appointed acting assistant-surgeons from Jan. 23, 1903.

Asst.-Surgeon M. V. Stone, detached from the Naval Training Station, Newport, R. I., ordered home and granted sick leave for two months.

Asst.-Surgeon W. E. G. High, ordered to the Naval Training Station, Newport, R. I.

Asst.-Surgeon J. S. Taylor, ordered to report to the Chief of Bureau of Medicine and Surgery, Navy Department, for duty.

A. A. Surgeon A. W. Kaines, ordered to the *Gloucester*.

Marine-Hospital Changes.

Official list of the changes of station and duties of commissioned and non-commissioned officers of the Public Health and Marine-Hospital Service for the seven days ended Jan. 29, 1903:

Assistant Surgeon-General H. D. Geddings, detailed to represent the service at meeting of Ohio Health Officers at Columbus, Ohio, Jan. 29-30, 1903.

P. A. Surgeon E. K. Sprague, granted leave of absence for six days from Jan. 15, 1903, under provisions of Paragraph 181 of the regulations.

Asst.-Surgeon M. H. Foster, to report to chairman of board of examiners at San Francisco, Feb. 16, 1903, for examination to determine his fitness for promotion to the grade of passed assistant-surgeon. Jan. 27, 1903.

Asst.-Surgeon L. L. Lumsden, to report to chairman of board of examiners at San Francisco, Feb. 16, 1903, for examination to determine his fitness for promotion to the grade of passed assistant-surgeon. Jan. 27, 1903.

Asst.-Surgeon B. S. Warren, granted leave of absence on account of sickness, for one month from February 1. Jan. 29, 1903.

Pharmacist L. P. Hall, granted leave of absence for seven days from Jan. 9, 1903, under the provisions of Paragraph 201 of the regulations.

BOARDS CONVENED.

Board convened at Washington, D. C., for the physical examination of an applicant for position in Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General W. J. Pettus, chairman; Asst.-Surgeon B. S. Warren, recorder.

Board convened at the marine-hospital, San Francisco, Feb. 16, 1903, for the examination of Asst.-Surgeons M. H. Foster and L. L. Lumsden to determine their fitness for promotion to the grade of passed assistant-surgeon. Detail for the Board: P. A. Surgeon W. G. Stimpson, chairman; P. A. Surgeon C. H. Gardiner; P. A. Surgeon H. S. Cumming, recorder.

Health Reports.

The following cases of smallpox, yellow fever, cholera and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended Jan. 31, 1903:

SMALLPOX—UNITED STATES.

California: Los Angeles, Jan. 4-17, 6 cases; San Francisco, Jan. 11-18, 8 cases.

Colorado: Denver, Jan. 10-17, 9 cases.

Illinois: Jan. 17-24, Chicago, 11 cases, 1 death; Galesburg, 1 case.

Indiana: Evansville, Jan. 18-24, 1 case, 1 death; Indianapolis, Jan. 10-17, 37 cases, 6 deaths; South Bend, Jan. 17-24, 5 cases.

Kentucky: Lexington, Jan. 17-24, 4 cases.

Louisiana: New Orleans, Jan. 17-24, 2 cases.

Maine: Aroostock County, Presque Isle included, Jan. 20, 150 to 400 cases; Biddeford, Jan. 17-24, 10 cases.

Massachusetts: Jan. 17-24, Boston, 5 cases, 3 deaths; Cambridge, 1 case; Chelsea, 1 case.

Michigan: Grand Rapids, Jan. 17-24, 21 cases.

Missouri: St. Louis, Jan. 18-25, 17 cases.

Nebraska: Omaha, Jan 17-24, 6 cases.

New Hampshire: Manchester, Jan. 10-24, 7 cases; Nashua, Jan. 17-24, 1 case.

New Jersey: Jan. 17-24, Camden, 1 case; Newark, 8 cases.

New York: New York, Jan. 17-24, 1 case.

Ohio: Chillicothe, Jan. 17-24, 1 case; Cincinnati, Jan. 16-23, 8 cases; Cleveland, Jan. 17-24, 14 cases, 3 deaths; Dayton, Jan. 17-24, 5 cases; Hamilton, Jan. 17-24, 2 cases.

Pennsylvania: Erie, Jan. 17-24, 9 cases; Johnstown, Jan. 18-25, 2 cases; McKeesport, Jan. 17-24, 5 cases; Philadelphia, Jan. 17-24, 13 cases, 2 deaths; Pittsburg, Jan. 17-24, 23 cases, 4 deaths; Reading, Jan. 19-26, 1 case.

South Carolina: Charleston, Jan. 17-24, 3 cases.

Tennessee: Memphis, Jan. 17-24, 8 cases.

Wisconsin: Milwaukee, Jan. 17-24, 3 cases.

SMALLPOX—FOREIGN.

Austria: Prague, Dec. 27-Jan. 3, 9 cases.

Belgium: Antwerp, Dec. 27-Jan. 3, 6 cases, 3 deaths; Ghent, Dec. 21-Jan. 3, 3 deaths.

Canada: Amherstburg, Jan. 17-24, 2 cases.

Great Britain: Birmingham, Jan. 3-10, 1 case; Dublin, Jan. 3-10, 1 case; Glasgow, Jan. 9-16, 1 case; Leeds, Jan. 3-10, 3 cases; Liverpool, Jan. 3-10, 59 cases, 6 deaths; London, Dec. 27-Jan. 10, 5 cases; Manchester, Jan. 3-10, 6 cases; Sheffield, Dec. 27-Jan. 10, 4 cases.

Russia: Dec. 27-Jan. 3, Odessa, 4 cases; St. Petersburg, 18 cases, 5 deaths.

Straits Settlements: Singapore, Dec. 6-13, 2 deaths.

YELLOW FEVER.

Colombia: Panama, Jan. 12-19, 6 cases, 2 deaths.

Mexico: Tampico, Jan. 10-17, 2 deaths.

CHOLERA.

Egypt: Alexandria, Dec. 28-Jan. 4, 9 cases, 6 deaths.

Java: Batavia, Dec. 6-13, 1 case, 1 death.

PLAGUE.

India: Karachi, Dec. 13-20, 25 cases, 13 deaths.

Address.

IDEALS IN MEDICINE.*

NORMAN BRIDGE, A.M., M.D.

EMERITUS PROFESSOR OF MEDICINE, RUSH MEDICAL COLLEGE, CHICAGO.
LOS ANGELES, CAL.

The career of every man is made in part by his opportunities, his powers, his equipment for the particular work and by the accidents of life. It is made quite as much by the plan and conception of his work and of himself, with which he starts out—and these are his ideals; and the ideals of no two men are ever exactly alike.

That a man's ideals are his making or his destruction is a very old truth, but it refers mostly to the cardinal virtues. The standards of honesty, truthfulness, uprightness and personal cleanness are the teaching of the best of all time. They are the indispensable ideals. To enlarge on them now would be to preach a sermon, and that is not a part of this program.

I would rather present some of those usually forgotten or unthought of ideals, those hidden standards that guide and govern the life in unexpected and surprising ways. These are numerous and varied, and nearly always possess a man without his knowing it; often without his friends knowing it. But they are automatic and never stop, and they control a man like a fetish. They are the hidden leaks that lose the wine, or some undiscovered supply that increases it. A man may forget for an hour his good resolutions or his religion, but these stealthy, idealistic guides will stick to him like his habit of breathing—they work with the certainty of subconscious mind. These ideals create habits that control us inevitably—and we are often ignorant both of the ideals and the habits they have created.

What are ideals for? To make an upright life? Yes, but also to make a successful one; to increase our power to do for ourselves and for others.

The greatest success on the average comes to those with symmetrical powers and character; not to those who are warped and one-sided. That ideal is of most worth which makes a man stronger in his weakest power; that is most worthless that increases his unbalance and accentuates his warping. Wherefore there are fit and unfit ideals.

But the surprising paradox is that, apart from the greater virtues, the ideals a man usually selects or becomes in some way committed to—what we may call his secular ideals—are unfit; that is, they are such as increase rather than lessen his asymmetry.

The reason for this is not strange—our ideals of this sort come to us along lines of least resistance. The reverse ought to be the case; we need ideals that will help us over our defects, not to increase them.

We do the same thing many times in our educational methods. A boy selects as the branch to study that which he learns easiest and knows most about, and neglects the tasks that for him happen to be harder. This tends to make the great talent greater and to let the lesser talent atrophy. When carried to an extreme degree this state of things constitutes genius; carried a little farther it is degeneracy, and the world is not sufficiently in need of geniuses to make degeneracy, or even the borderland of it, profitable.

The sometime gospel of pedagogy has said that the child, from the beginning, may select his course of study—learn what he likes and omit what he pleases. Of course, he likes those things in which he is apt and strong, and hates those hard ones in which he is weak—and so he grows more uneven. Happily, all educators do not agree to this tenet; some believe that a child's course of study should tend to make a symmetrical man, not favor asymmetry. This is logically the part of wisdom.

Thus of a man's ideals. They ought to contribute to his power and increase his happiness. But unfit ideals—both positive and negative—are the source of a great amount of grief, failure and chagrin. That man who knows (from his examination papers or otherwise) that his use of English is crude and blundering, should have the perfection of the language for one of his ideals, and try to acquire a critical sense of it. But this is the very thing he is least likely to do, both because his consciousness of his fault is dull and because the ideal is hard. The lack of such an ideal has kept many a man below his deserts and sometimes even blasted a career. I know of several notable examples of this sort. One was a man of great superiority in the science of medicine who failed of appointment to an important professorship he had coveted for years, and for no other reason than the lack of such an ideal.

If a man could know that in his demeanor he is liable to be rude, brusque and impolite (as his neighbors know it) he might erect an ideal of gentleness and courtesy with great profit to his spirit, and, if he practices a profession, profit to his purse also. Probably he has already fully or over-developed powers in other directions, most likely in force and effectiveness. Can he discover the need of a new ideal and create it? Perhaps he can, but nothing short of a new birth in introspective psychology will enable him to do it.

On the other hand, the man who is naturally courteous and thoughtful of the feelings of others in little things,

* An address delivered at the Commencement Exercises of Rush Medical College, in affiliation with the University of Chicago, Oct. 2, 1902, the introductory remarks being omitted.

and especially in the entertainment of others, is in danger of overdoing a good ideal. For it can be carried so far—and often is—as to entail a burden in the manifold duties which it imposes. It is a greater burden in the fear, dread and terror it often produces in its possessor lest it may be violated. And when it is in excess it has no compensating advantages, except some very dubious ones. The standard requires the person to be polite and to entertain others in conversation—so a sick man wears himself out entertaining thus a lot of people to whom he is under no obligation. A distinguished friend, when on his death-bed and too weak to talk to anybody, actually felt called on to apologize for not talking. The ideal sometimes grows to be a sort of craze—not only to talk, but to believe it a duty to talk whenever within earshot of others. Then follows a species of deception and finesse—for we get tired of people, even our friends, and tired of talking to them; so we shun them, keep out of their way, avoid them, give a lot of fictitious excuses for not coming and for being out. For we know perfectly well that once in their presence nothing but syncope or death can stop the wagging of our tongues. That we have enough of plain courage to stop it, is unthinkable!

Ideals as to personal appearance, dress and adornment lead to many bypaths that take us into unexpected regions. Sometimes the effect is grotesque in its influence on character and success in life. The sum total of it is usually unfortunate, if not bad, the one advantage being the happiness which the individual himself seems to get out of his indulgence. It is a cheap sort of happiness, always yoked with a degree of vanity, but some people can be made happy by such things. Once there was a judge in the east who, for a quarter of a century, appeared daily with his hair wrought into large curls. It was inevitable that it should influence his character and his relations with others. Not that the curls amounted to anything *per se,* except as they singled him out from among the rest of the community, but solely through the introspecting influence, the egoism which is engendered in the man.

If it were the custom for men to wear rings in their noses it would mean little except a thraldom to a mere fashion—a thing we are constantly victims of. Fashion allies us to a race, a guild or a set of people. For one man in a hundred thousand to wear a ring in his nose takes him conspicuously *out* of the fashion and into the realm of vain conspicuousness.

The curls of the judge even failed as a mark of defiance of that fashion whose purpose is show. Such a defiance would have required a fine sort of courage and independence. If that kind of fortitude had been required in order to wear the curls he never would have had them. It needed only a species of vanity, a desire to do something others did not or could not do, something that would distinguish this man from all his fellows; or an abounding desire to please his personal fancy. It was different, too, from a wholesome desire to distinguish the self from others. That could have been sought through work, art, achievement, skill or daring—what countless thousands of men and women are doing every day. This took no courage worthy of the name, no work—save a few minutes each morning with his curling facilities—no attainment, or study, or skill. He paraded his curls like the color of his skin, or the shape of his features, or the gait of his walk, and without a particle of credit of any kind.

Now the curls were a trifle, like an inch-long fingernail or a beard the length of the body. These are all little things in themselves and amount to nothing in the world's greater arithmetic. But they are vital if they signify a mental quality, an emotion, which colors the life and segregates in some way an individual from his fellows—and they always mean a weaker rather than a stronger purpose. They are more lamentable still if they beget, as they tend to, an emotion that lessens the power of the individual in the world. Such a waste of personal force and influence is a sin.

It is no adequate reply to the criticism to say that such habits are happifying to the individual, for joy can come as truly from ennobling and developmental emotions as from weak and minifying ones.

To make oneself odd by defying a useless or injurious fashion, when it takes courage to do it, is commendable. That is to defy the class conscience and take a stand for the sake of individual conscience. The fashions in trifles, like neckties and ribbons, is the refuge for souls that lack courage. To refuse to use tobacco or liquor, or wear high collars or tight corsets, sometimes takes the manner of courage that pushes a man into battle, or makes him face an epidemic of deadly disease and not run away from it. No case can be made out against such courage—it can not even be laughed down.

There are some ideals which a practitioner of medicine can not afford to do without, as there are those he ought to shun with all his power. One of the latter that is very common to us is that of our own certainty and sufficiency. We fall into it unavoidably. We have, we believe, the very foundations of all wisdom, and we are bent on reforming the world, if not making it over, in the first decade. So there grows up within us a great amount of dignity and personal importance that is sure to be jarred by sundry experiences of life. But we feel bound to protect and defend them, nevertheless. When a patient fails to take the medicine as ordered, or otherwise ignores our advice, we are affronted and get warm or grieved over it, and so waste a store of good energy that we might put to a better use.

It is a slow lesson that people have notions of their own—foolish ones often—which they have been following very much for centuries, and that they have some rights to follow them, even if they are foolish; also, that they frequently will follow them in spite of any and all of our efforts to the contrary. And we gain less rapidly when our sense of independence and personal importance runs against theirs. It is a long step forward when the young physician can say to the misbehaving patient, and say it gently: "Of course, you do not *have* to take the medicine I prescribe or to follow my advice. They are both given on the theory of doing you good, but you can omit them if you wish; only remember that if you do omit them, not I, but you, take the responsibility. I am willing, even glad to be freed from responsibility if you wish me to be." Say that and see how quickly the moral atmosphere will change.

Have an ideal that you will do your work honestly, faithfully, not lazily or carelessly; that you will keep written records of your work and not trust to your memory of it, and that then you will take the consequences without grumbling or whining. This is of the very essence of the best courage. Moreover, after you have planted your seed as best you may, watch for its sprouting, but don't dig up the ground to see if it has sprouted or is growing downward.

Shun the vicious ideal of speculating in your mind

as to what in general others think of you. Don't walk down the street metaphorically asking people whether they recognize in you the sort of a fellow you think you are. To do it distracts the mental attention and prevents serious work; or leads to worry, fear, suspicion, jealousy and heart-burnings. It doesn't pay. And when you begin to guess—for many will, and usually guess wrong—as to how others think and feel about you, then you are walking along the rim of the grand canyon of gentle lunacy. You may never do it—pray that you never will—but you can then very easily plunge over into the canyon.

I once had a friend, eminent in the profession, who, when called in an emergency to see a patient of another physician in his absence, always prescribed with ingenuous loyalty, both to the patient and his physician. But he would go round the next day and make an unexpected call on the patient. When asked why he did it, he said: "I do it to see how I stand with the family." He was a good man in most things, but he was wrong in this, and the foolish ideal tinged to his discredit his whole career. He had no call to constitute himself a detective to find out whether the people thought well or ill of him—and it was little advantage if he did know, for if it was well his vanity grew, which was needless, and if it was ill he increased his bitterness, which was unnecessary. His duty ended when he had served the patient honestly and scientifically, and he ought to have had the courage to rest his case there. His duty, like the duty of all men, was to know himself that his conduct was correct and that it tallied with the Golden Rule.

One of the best ideals of all is that we will not and can not afford to be petty and trifling. This is a hard one to hold to, so naturally do we fill our heads with the trivialities of life. We talk about trifles, hear about them by the hour, and read them in the columns of personal gossip in the daily papers. If you care for a curious study in the anatomy of your own daily life, just make a list every night for a week of all the trifles that have concerned your mind during the respective days, and lay the record aside for a year. Reread it then, and say whether you think it was a profitable week.

One of the hardest things of all to do—and one of the most important to be done—is to make sure that we do not regard to-day that thing to be momentous which to-morrow we shall know to have been a trifle. The struggle after real consistency is a hard one.

One of the greatest achievements of a young physician is to be able to be dismissed by a patient and be serene about it. It is a question of point of view and the relation he thinks he holds to his patients. If he has the only right view, namely, that he is a servant of the public, and that his relations with his patients must be of absolute mutualness, and that he most of all desires that the relations shall cease the moment the mutualness is broken—if he can get himself up to this platform he has smooth sailing—otherwise, he encounters repeated seas of hot water that rob him of many of the joys of life.

Numerous physicians go through life with such false and artificial notions about their fees as to create for them a lot of trouble. Their difficulties are chiefly of two kinds. One is an unreasoning idea, acquired out of nothing and from nowhere, that all patients must be averse to paying for their medical services, and resent being asked to pay. So the young physician is likely to feel that sending a bill, and particularly the dunning of a patient, has some of the qualities of a challenge to combat; and that it will be at best a very unpleasant task. This is all wrong; the average patient expects to pay a fair fee for faithful attendance, and to take the contrary view discredits both the physician and the public. Of course, there are a few men and women who have no appreciation of their just obligations, and always try to shirk them—but they are the exception, and we ought to be willing to teach them some lessons by wholesome insistence, and to do it without anger and without looking or acting as though we had been stealing.

The opposite ideal with which a few start out is that of coveting the enormous fees they have heard of a few men receiving. This attitude is unfair to the people, who should only in the rarest instances be expected to pay such sums—and can only in a few cases afford to pay them—and it does the physician discredit, since it begets a spirit of sordidness, and works against the best service of the profession to the public, which is one of the most sacred of all the duties of the physician.

Let us first be scientific and faithful to our patients; let us acquire friends and a large clientele if we can; then let us raise our fees to keep down a flood of work that happens to flow our way. When, if it ever comes, something leads the public and the profession to make a large enough market for such talents as we have, then let our fee bills to those able to pay recognize the fact, but let us never, as we hope for future happiness, be grasping with the poor people who give the world its best lessons in frugality and honesty; and let us, as we hate meanness, never forget our own days of small things.

Let us be honest to science and to ourselves. If we have to shade the fact to the patient for his own good, and even to give him placebos to the same end, we must never deceive either science or ourselves. There is only one right way to study and practice medicine, and that is in a spirit of humility to the truth, and especially to the new truth—but to the truth proven.

Probably the most effective mental quality that most young practitioners lack—that few men have at beginning—is the power of imperturbability. No other quality so makes the physician superior to accidents, emergencies and trouble as this; as no other is so profitable in making his reputation as a power.

If a patient dies on the operating table, or goes out in a minute from pulmonary hemorrhage, or if you discover you have blundered, you must not shake; and you must not throw up your hands while life lasts. However appalling the emergency you must not be dismayed; and you must make your best fight when the tide sets against you. In athletic games that man is worth little who can only play his best when victory and the shouts of his friends are in the air. So in this professional life, the man who is strong only when no calamity threatens is worth little. In this civilian career the best quality of a soldier is needed, that quality is dependableness in times of trouble.

Finally, there are a few ideals that are so vital for an all-round success that they are sacred. One is that this business of life is too important for us to waste time and energy in contentions for personal ends. If we contend it must be for some principle or for a benefit to the public whose servants we are. There is one sovereign remedy for all personal quarrels that anybody may attempt to get you into—that is to ignore them and go on

with your work. If you will only have pleasure in this and let it fill your days, you will have no time to contend, and your neighbors will soon know the fact.

Another ideal, and the most sacred of them all, is one of discontent—a discontent that must only end with your latest breath of mentally competent life. You must be dissatisfied with the many unsolved questions of science, problems of the greatest interest; problems that concern the lives of all the people. It is an unending work of love and interest to solve them; and the long night of our past ignorance about them must not discourage you. So much new science has come by the labors of our profession within the memory of men still young, that nobody should be discouraged as to the future. Cancer will be understood and pernicious anemia and diabetes, and a hundred other diseases, and the greatest enemy of all, tuberculosis, will be controlled—and toward these ends every man can contribute. If you can not become an investigator you may help hold up the arms of another who is, and so shall have some part in the cumulative consummation. Stirred by this discontent your eyes must look steadily forward for new light—beware of the false ones—for the true light will appear and you shall not be surprised because you have been looking for it all the years—so shall you grow and learn to your latest day, and you shall escape mental fossilization. This deplorable fate of so many physicians comes of a fixed notion that most of the knowable is known, and that science will remain as it was. But whoso postulates that many things are yet to be discovered, and that some of his most precious theories may one day have to be given up or recast, and that it is a disgrace to stand still—that man will keep his heart warm and his interest close to the moving column. He can never become a mental fossil; and though living into age he shall die young.

The medical profession must progress and grow in knowledge, and the new knowledge must make for higher usefulness. But we are in danger—and the more volatile of us in most danger—from this very fact. We are liable if not likely to be side-tracked in a pursuit of one idea and to be governed by it, and so lose our sense of proportion; to become seized with a fad and try to square the world with it. The rapid progress of our science and art during the past few years has increased this danger, and we have had plentiful examples of medical men being dominated by a single thought, and losing all judicial judgment. Some of the more enthusiastic of them have had a new fad each decade for forty years. Hardly one of them has attained to great success in any way, unless the occasional riding into pecuniary fortune, possibly in the saddle of their fads, may be called success.

No professional man has great success merely because he makes money—success requires also usefulness to his public, loyalty to the truth, the approval of the great body of his associates, and a clear conscience of his own. Thorough sanity and moderation in all our judgments is, therefore, the only safe ideal, and there is more need now than ever before for this standard in the medical profession. To "prove all things; hold fast to that which is good," has not ceased to be wisdom. We can be progressive and be sensible also.

We can be moderate and judicial, refuse to be stampeded either for or against a new doctrine, and yet put every new truth to its best use. We have no warrant, simply because we have discovered a new fact, to throw our hats into the air and forget that this fact has important relations with a hundred old truths that can not be abandoned, and we will show our wisdom by searching for those relations. If complete salvation ever comes to us it must be through all the truth, not a mere fragment of it. And a due sense of proportion—otherwise common sense—as an unswerving and insistent ideal is, in a work-a-day life, the best guide for a safe journey.

Original Articles.

THE CHEMISTRY OF THE TROPEINS.*

A. B. LYONS, M.D.
DETROIT.

It is now more than seventy years since Mein announced the discovery in belladonna of an organic base. The discovery was made independently two years later by Geiger and Hesse, who in the same year discovered in stramonium a similar base to which they gave the name daturin, also in henbane another which they called hyoscyamin. It is needless to follow the details of the subsequent investigations which even yet are not complete. Suffice it to say that they have led to the conclusion that the bases discovered in the several mydriatic drugs, belladonna, stramonium, henbane, mandragora, duboisia and scopola, and named at first from these respective drugs, atropin, daturin, hyoscyamin, mandragorin, duboisin and scopolamin, are mixtures chiefly of three or possibly four alkaloids, two of which, atropin and hyoscyamin, are isomeric; the other two, if we adopt the views of O. Hesse, are also isomeric, although differing somewhat in atomic composition from the former. All have the property of producing extreme dilation of the pupil of the eye, but it is probable that no two exactly coincide in their physiologic or medicinal action.

There has been a good deal of confusion in the past in the nomenclature of these alkaloids. In the first place the alkaloids, and so the products of manufacturing houses, have generally contained more than one of the alkaloids. Atropin in particular has frequently contained a large proportion of hyoscyamin, while commercial hyoscyamin contains always some atropin. More serious than this, however, is the confusion that has arisen from the use of the term "amorphous hyoscyamin," applied to the residual alkaloid from henbane from which hyoscyamin has been removed. This residual alkaloid was rightly believed to represent the characteristic action of henbane as distinguished from that of belladonna, and, in fact, consisted chiefly of what is now commonly known as hyoscin, the distinctive alkaloid of henbane. When the crystallized hyoscyamin appeared physicians naturally supposed that it was simply a purer product, and they have been rather slow in discovering that in its action it resembles more nearly atropin than the amorphous hyoscyamin they had formerly used.

The confusion was increased when later a crystalline salt of hyoscin was produced, not from henbane, but from *Scopola atropoides,* and was offered under the name scopolamin hydrobromate. Then, finally, the physician learns that the principal alkaloid of the common European scopola is hyoscyamin, and he couples this fact with the information that has come to him that scopolamin is identical with hyoscin, and concludes,

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, and approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

very naturally, that hyoscyamin, which he supposes is the distinctive active principle of henbane, is identical with hyoscin.

Now the facts are that: 1. Hyoscyamin is the most widely distributed of the mydriatic alkaloids, being found in belladonna, stramonium, henbane, duboisia, mandragora and scopola; in fact, in every solanaceous plant possessing mydriatic properties. It has been reported even as present in lettuce, a plant of a different family, but the announcement seems to want confirmation. 2. Hyoscin, on the other hand, while present in minute quantity in most mydriatic drugs, is an important constituent only of henbane and of *Scopola atropoides*. 3. Hyoscyamin is easily converted into atropin, so that it is the latter alkaloid rather than the former that is obtained by the ordinary manufacturing processes, even when the drug originally contained chiefly or only hyoscyamin.

I may add that chemists are not as yet wholly agreed as to the nomenclature of these alkaloids. There is no longer any disagreement regarding the names atropin and hyoscyamin, but some chemists prefer the name scopolamin to hyoscin, the latter having been originally applied to the "tropin" derived from hyoscyamin. O. Hesse, while adopting the name hyoscin for the distinctive alkaloid of henbane, finds that commercial scopolamin is a mixture of this with another isomeric alkaloid to which he gives the name atroscin, and his views are now widely accepted.

According to principles generally recognized in scientific nomenclature, the name hyoscin should be ruled out as having been originally applied to a different substance. The principle is "once a synonym, always a synonym." The later name, scopolamin, would stand next in succession, but to which of the two alkaloids should it be applied? The fact that scopolamin was identified with hyoscin before it was discovered that the former consisted of two different alkaloids should decide us to retain the name as synonymous with hyoscin, which name must be abandoned for the reason just given. It is true that from 40 to 80 per cent. of commercial scopolamin consists of the more recently discovered alkaloid, but that is no reason why we should not adopt the new name proposed for it by its discoverer. This name, atroscin, is, moreover, etymologically appropriate. It suggests the idea of kinship at once with atropin and with hyoscin—although the hyoscin in question is improperly so called. Dr. Hesse maintains that his atroscin is related to scopolamin (hyoscin, he calls it,) in precisely the same way that atropin is related to hyoscyamin.

This brings us to the question of the relation to one another of atropin and hyoscyamin. The two alkaloids have the same ultimate composition, the empirical formula of each being $C_{17}H_{23}NO_3$. The chemical behavior of the two is almost identical, but corresponding compounds differ materially in physical properties, and by taking advantage of such differences the alkaloids may, with some difficulty, be separated. Thus, of the aurochlorids, that of atropin is much less soluble in water, and accordingly when a solution of gold chlorid is added drop by drop to the mixed hydrochlorids of atropin and hyoscyamin the precipitate which forms at first consists almost wholly of atropin aurochlorid. The precipitate is amorphous, having a melting point of only 135 to 138 C. When crystallized from its solution in boiling water, acidulated with hydrochloric acid, it takes the form of minute crystals, which, after drying, are without luster. The corresponding compound of hyoscyamin forms a crystalline precipitate consisting of golden yellow scales which retain their luster after drying, and have a melting point of 160 to 162 C.

Atropin itself has a melting point of 114.5 C. and crystallizes in needles or minute slender prisms. Its solutions are optically inactive, i. e., they do not rotate the plane of polarization of a ray of polarized light. Hyoscyamin has a melting point of 108.5 C., considerably lower, therefore, than that of atropin. It crystallizes in very slender needles, frequently in radiating clusters. Its solutions turn the plane of the polarized ray strongly to the left. When hyoscyamin is heated to a temperature slightly above its melting point, or kept in contact with solutions of potassa, soda or even of ammonia, it is gradually converted into atropin.

The latest researches indicate that it is probably hyoscyamin which is formed at first in the plant in all cases. The flowers and young leaves and shoots of plants like stramonium or belladonna yield chiefly or wholly hyoscyamin. Mature plants and old roots yield mainly atropin. In the ordinary processes of manufacture no doubt a large proportion of the hyoscyamin is converted into atropin.

If it turns out that there is a decided difference in medicinal action between the two alkaloids, it will become a matter of importance at what season such a drug as belladonna is collected. Even soil and climate may be found to have a heretofore unsuspected significance in connection with these drugs. It has been recently observed that stramonium grown in Egypt contained no alkaloid but hyoscyamin. An Indian species of henbane, *Hyoscyamus muticus*, yielded also almost pure hyoscyamin, and the same plant grown in Egypt was found extraordinarily rich in that alkaloid. The European henbane yields, beside its characteristic alkaloid, scopolamin (or hyoscin), both atropin and hyoscyamin.

According to Dr. Hesse, scopolamin (hyoscin) corresponds with hyoscyamin; atroscin with atropin. Both scopolamin and atroscin have the empiric chemical formula $C_{17}H_{21}NO_4$. Scopolamin melts at 55 C. It rotates the plane of polarization to the left. It may probably be converted into atroscin by the action of alkalies, the latter alkaloid being optically inactive, and having a fusing point at 82 to 83 C. Since the views of Dr. Hesse are not universally accepted, I ought to state that the old view, that the so-called hyoscin from henbane is isomeric with atropin and hyoscyamin, is still held by some chemists, the relation which this hyoscin bears to scopolamin from *Scopola atropoides* remaining undetermined.

Regarding the chemistry of atropin and hyoscyamin, however, the facts, which are of unusual interest, are well established. By the action of alkalies or of mineral acids, the alkaloids are readily "saponified" or split into a basic and an acid constituent. This saponification or hydrolysis is most conveniently effected by baryta, and results in the formation of tropin and tropic acid according to the equation $C_{17}H_{23}NO_3+H_2O=C_8H_{15}NO+C_9H_{10}O_3$. Under the influence of acids the reaction is $C_{17}H_{23}NO_3=C_8H_{15}NO+C_9H_8O_2$, atropic acid being formed in place of tropic acid.

Tropic acid and tropin can be made to recombine, although the union is not precisely of the same kind as that between acid and base. What is more interesting and more important is the fact that tropin may be made to combine in a similar way with other organic radicals forming new synthetic alkaloids. Ladenburg, who first established these facts, gave to these alkaloids the gen-

eric name *tropeins,* this name applying equally to the natural and to the synthetic alkaloids.

The other alkaloids found in Nature associated with hyoscyamin and atropin are also tropeins, or else are similarly constituted so that they are saponified by the action of baryta, some of them yielding, instead of tropin, an isomeric base called pseudotropin. According to Dr. Hesse, scopolamin and atroscin yield instead of tropin the base oscin, to which he assigns the formula $C_8H_{13}NO_2$. In the older view these alkaloids also are tropeins. The important facts are that they are split up under the action of alkalies and of acids in the same way that the tropeins are, and that they act on the pupil of the eye in the same way that the natural tropeins do. This characteristic property, it is interesting to note, does not belong to all the artificial tropeins, although possessed in a high degree by some of them. Benzoyl-tropin dilates the pupil strongly; salicyl-tropin, differing from the preceding only in having in its molecule one more oxygen atom, produces no such effect.

Accompanying hyoscyamin and atropin in belladonna and other mydriatic drugs, there have been found the allied alkaloids belladonnin and atropamin. These differ from atropin in containing the equivalent of one molecule of water (H_2O) less. They are, therefore, distinguished as anhydro-tropeins. It is not certain that these actually exist in the drug. They may possibly be produced by the action of the chemicals used in extracting the alkaloids. They are split up by baryta into an acid and a basic constituent, the former isomeric with tropic or atropic acid, the latter isomeric with tropin, but differing from that base in its properties and called pseudotropin. An allied alkaloid, yielding by saponification benzoic acid and pseudotropin, has been found in coca leaves, although it appears not to be a constant constituent of these. None of these alkaloids, so far as I know, are mydriatic. Some of them act as powerful irritants when applied to the conjunctiva. None of them are known to have medicinal properties of importance and they do not form a large constituent of the alkaloids in any mydriatic drug so far as is yet known.

Of the mydriatic drugs, only three, belladonna, stramonium and henbane, are used to any extent medicinally in this country. The two former are generally considered to have practically the same medicinal action, differing only in degree. If a distinction exists it has not yet been made a subject of scientific analysis. The action of henbane, however, is without question quite different from that of belladonna. All three drugs contain the three alkaloids, hyoscyamin, atropin and hyoscin (or scopolamin), but in different quantities and in different proportions. Belladonna is believed to contain generally chiefly atropin, although hyoscyamin may sometimes predominate. Stramonium probably contains generally more hyoscyamin than atropin, although this may prove to be not uniformly true. Henbane contains relatively a much larger proportion of hyoscin (scopolamin) than either of the other drugs. Good belladonna leaves should yield of total alkaloids as much as 0.30 per cent., the proportion varying, however, between 0.1 and 0.5 per cent. or more. Belladonna root contains generally more alkaloid than the leaves, but the drug varies greatly. Stramonium leaves should yield 0.25 per cent. total alkaloids, the proportion ranging from 0.1 to 0.4 per cent. Henbane contains very little alkaloid. If it yields to assay 0.1 per cent. total alkaloids, estimated as atropin, it is of exceptionally good quality.

From the great variability of these drugs in strength it is exceedingly desirable that we should have reliable assay processes by which to ascertain their quality and that certain standards should be fixed by the pharmacopeia as minima of strength for each. Satisfactory assay processes are as yet a desideratum. As long as we are in doubt whether there is any important difference between the therapeutic action of hyoscyamin and that of atropin, the result of an assay that determines only total alkaloid leaves much to be desired. Particularly is this true when there are liable to be present also other alkaloids, such as atropamin and belladonnin, which are medicinally inert, or which may produce even undesirable effects. Under such conditions all that we can hope to learn from an assay is whether or not there is present a minimum amount of something which contains the active principle of the drug, and probably consists largely of that active principle. In view of the fact already stated, that specimens of the drug are often met with which contain less than 30 per cent. of the quantity of alkaloid ordinarily present, even such an assay is of distinct value.

But suppose an assay is made of belladonna leaf or of belladonna root, which are really not belladonna at all, but scopola—and this is a very common substitution —the drug will be reported to contain a normal amount or very possibly much more than the normal amount of alkaloid, with no hint that this consists mainly of hyoscyamin and not atropin. We have no method as yet of effecting a quantitative separation of these two alkaloids when dealing with the minute quantities obtained in ordinary assays, rarely more than 40 or 50 milligrams, but we may resort to the polariscope, and with a sufficiently sensitive instrument we may be able to determine approximately how much of the alkaloid is hyoscyamin, in absence of other optically active alkaloids. Much experimental work would have to be done before we could be sure that the results were trustworthy.

Possibly some satisfactory method may be devised of testing the strength of these drugs empirically, i. e., by the so-called physiologic method. We are certainly not in position as yet to devise any such method of testing. If it were possible to measure accurately the mydriatic action of the drug we should still have to determine accurately the mydriatic action of each of the alkaloids present, and it is easy to see that if there are more than two of these we shall have a greater number of unknown quantities than we have of equations.

The assay of henbane is still further complicated by the undoubted fact that the characteristic effect of the drug is produced by the third alkaloid, hyoscin (scopolamin), or by the combined action of this with hyoscyamin. The total quantity of alkaloids, moreover, is exceedingly small. The most we can hope to do is to ascertain whether the drug contains as much as a certain proportion of total alkaloid, but even this is not so simple a matter as at first appears. The alkaloids themselves are very easily changed by the action of the chemicals used in extracting them. The accidental presence even of a few drops of alkaline water during the final evaporation of the ethereal solution of the alkaloid may reduce the apparent yield 50 per cent. or more. After every precaution has been used to avoid change or loss of alkaloid, we have still the problem of determining how much alkaloid we really have. Our product is so impure that we can not rely on weighing it. We must ascertain its neutralizing power, and from this calculate the weight. But the neutralizing power of

hyoscyamin is not precisely the same as that of hyoscin (scopolamin), so that we must use a mean value or else report our alkaloid in terms of hyoscyamin, or of atropin, which amount to the same thing.

The polariscope can not aid us very much because both hyoscyamin and hyoscin (scopolamin) are levorotatory. There is one important difference probably. Hyoscyamin combines with a larger proportion of iodin than hyoscin under similar conditions. Possibly this may serve to show approximately the relative proportion of the two alkaloids, but this is a suggestion that must be worked out experimentally. Up to the present time we certainly have no satisfactory way of determining the therapeutic value of a sample of henbane, except by actual trial—the method that our fathers had to use before us.

I speak of these things, not to belittle the value of chemical assays. I am a firm believer in such assays. I have full confidence that science will overcome the obstacles that seem now almost unsurmountable; that the day is not far distant, indeed, when the particular difficulties which surround the assay of mydriatic drugs will have been conquered. But this can only be hoped for if we clearly understand the nature and the magnitude of the difficulties.

Recurring now to the tropeins as compounds of some organic acid with tropin, I call attention to the peculiar interest which attaches to the latter (basic) constituent by reason of its relationship with the organic base pyridin, and so with coniin and nicotin and with the decomposition products of cocain. It will not be profitable to enter here into the details of these relationships. It suffices to know that modern organic chemistry is rapidly mastering the intricacies of the molecular constitution of compounds so complex as the vegetable alkaloids.

That this knowledge is not purely transcendental, but capable of practical application, is proved by the fact that the chemist is able not only to reconstruct from its constituents, one of which he is able already to produce synthetically, the alkaloid atropin, but also to form new artificial alkaloids, one of which, homatropin, is already familiarly known as an article of the materia medica. Some of these synthetic alkaloids, as I have already said, have a strong mydriatic action; others little or none. A wide field is opened for useful experiment on their physiologic and possible therapeutic action.

Who shall pursue these researches and in what spirit shall it be done? Many of them will lead only to negative results. A few will lead to discoveries that will enable us to cope successfully with morbid conditions that now baffle our skill. Such rewards appeal to two classes: to men on the one hand whose profession binds them to unwearying, strenuous effort to possess themselves of every resource for the ministering to human needs; to men on the other hand who understand the commercial value of a new popular medicine. Which of these classes will be most likely to find the treasures that lie hidden in these new mines? Which will make such use of those treasures when found as will make the world richest through them?

The work, friends, is ours. To the toil it involves our lives are consecrated. To us alone is known the true value of the objects of this search. To us of right belong the honor and the glory of discoveries such as we hope for. It should be a shame to us to have to pay tribute to the mercenary explorer who has adventured more for gold than we for humanity—and the chance is that any such tribute is after all bare-faced imposition.

It is not alone the glory, it is the work, that is ours—patient, plodding, self-sacrificing toil, and the place above all others to do that work is right here in the Section on Materia Medica, Pharmacy and Therapeutics of the American Medical Association. It is our task; it is also our glorious opportunity. Let us see that the opportunity is improved.

THE PHYSIOLOGIC ACTION OF THE MYDRIATIC ALKALOIDS.*

HORATIO C. WOOD, Jr., M.D.
Demonstrator of Pharmacodynamics, University of Pennsylvania.
PHILADELPHIA.

The number of drugs which dilate the pupil is so very large, and the physiologic relations of many of them so distant, that a consideration of all those substances which might be called mydriatics would not only consume much more time than is at our disposal, but would necessitate classing together of drugs not naturally so related. I shall, therefore, confine my remarks to those alkaloids which belong to the series of tropins; and for similar reasons of brevity omit the consideration of the synthetic alkaloids of this series, such as homatropin.

Before, however, taking up the consideration of the physiologic action of these substances, I wish to call attention to the very unfortunate confusion in the nomenclature of the active principles of the solanaceous plants. As various investigators have from time to time discovered in different members of this family alkaloidal principles, they have given new names to their discoveries, which in many cases were subsequently found to be identical with alkaloids already described. Thus, for example, the active principle of *Datura stramonium* has been called daturin, it being in reality atropin; scopolin is synonymous with scopolamin; while the active principle of *Duboisia myropoides,* known sometimes as duboisin, seems to be a mixture of hyoscin and hyoscyamin. There are four of these mydriatic alkaloids occurring in Nature which have become of practical importance to the physician: atropin, hyoscin, hyoscyamin and scopolamin. These group themselves naturally into two pairs, atropin and hyoscyamin, hyoscin and scopolamin.

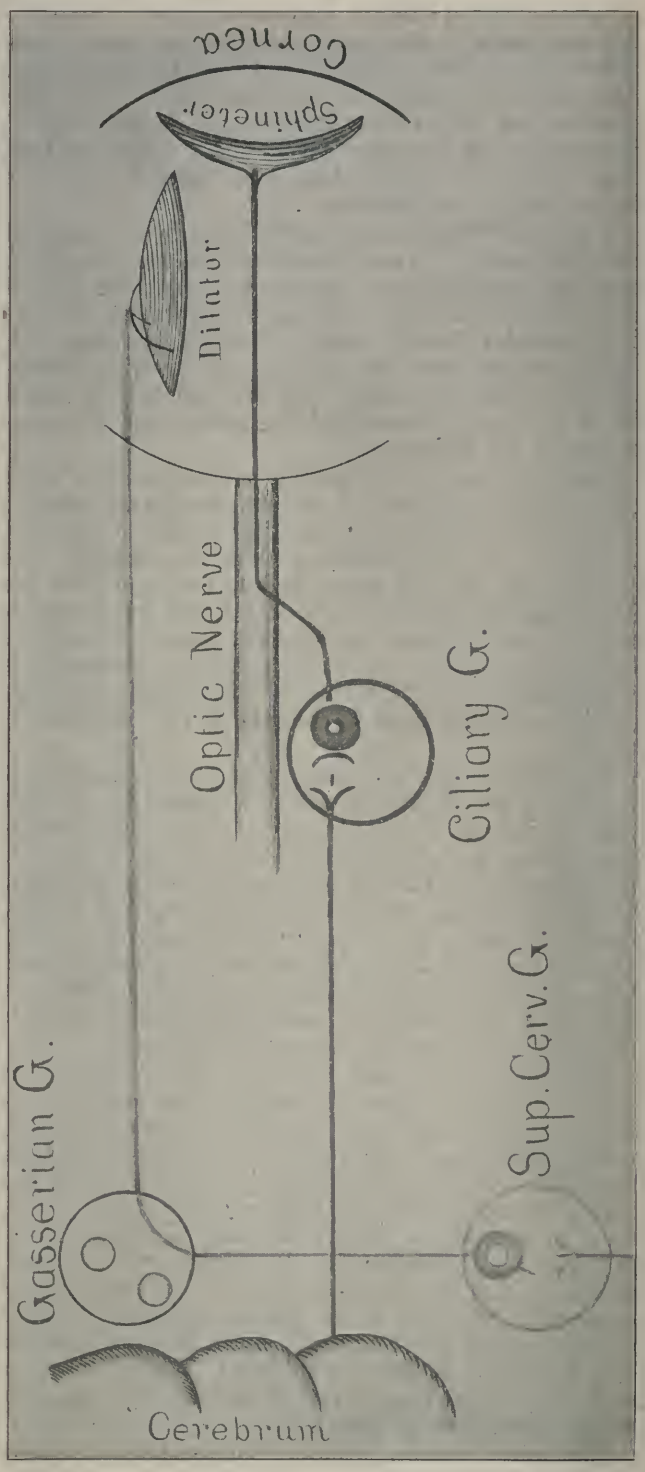
ATROPIN AND HYOSCYAMIN.

As closely allied physiologically to atropin as it is chemically is the isomeric alkaloid hyoscyamin. This is perhaps the most widely distributed of all the solanaceous alkaloids; it occurs not only in both *Atropa belladonna* and *Hyoscyamus niger,* but also in the *Duboisia myropoides, Datura stramonium,* and especially in certain species of scopolia; while atropin is found chiefly in belladonna and stramonium. The frequent substitution of the rhizome of *Scopolia carniolica,* the dominant alkaloid of which is hyoscyamin, for belladonna, renders the question of the comparative effect of these principles of great importance.

It is to be noted that of these two plants belladonna contains hyoscyamin and atropin, the latter being the dominant alkaloid; while scopolia contains hyoscyamin and hyoscin. The amount of hyoscin, however, present in the rhizome of *Scopolia carniolica* is so small as to have little bearing on the physiologic action of this plant, notwithstanding the contrary assertion sometimes made

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, and approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

by interested manufacturers. (This statement does not hold true of *Scopolia atropoides,* in which the dominant alkaloid seems to be hyoscin.) In an investigation which I made a year ago concerning the relations of *Scopolia carniolica* to *Atropa belladonna,* I was unable to detect any differences either between the action of hyoscyamin and atropin, or between scopolia and belladonna, except one of dose; and what I shall say of the action of atropin, therefore, applies also to hyoscyamin.



In generalizing the physiologic action of atropin the most characteristic effects seem to be a paralysis of the involuntary muscle fiber, a paralysis of the peripheral nerve endings and a peculiar stimulation of some of the higher nerve centers. The peripheral nerves which are most susceptible to the action of this substance are the cardiac inhibitors, the nerves regulating secretion and those which supply the pupils. Since we have grouped these drugs together on account of their action on the eye it is logical to consider this portion of the subject first.

Eyes.—Atropin has two effects on the eye: it dilates the pupil and paralyzes accommodation. These actions, although usually associated in the same drug, are not so of necessity. *A priori,* there is no reason why a drug might not either affect the pupil and leave intact the ciliary muscle, or vice versa, paralyze accommodation without alteration in the iris.

For the purpose of closer study of the manner in which atropin dilates the pupil, I have prepared a diagram representing the innervation of the eye, which will not only save a great deal of circumlocution, but perhaps make the subject clearer than a lengthy description. In the first place, we must remember that under the only condition in which it is possible to examine the eye, that is, in the presence of a certain amount of light, the sphincter pupillæ is always in a state of partial contraction. It is evident, therefore, that a drug may dilate the pupil, not only by stimulating the dilator mechanism, but also by paralyzing the contractor mechanism. If we glance for a moment at the diagram we see that these effects may be either on the centers governing these muscles, on the nerve trunks which carry the impulses from the centers, or on the muscles themselves. It is evident, therefore, that the pupil may be dilated, on the one hand, either by stimulation of the sympathetic ganglia, representing the dilator centers, or of the nerve which carries the dilator impulses to the muscle, or by a direct action on the radial fibers of the iris. On the other hand, the pupil may be dilated by paralysis of the contractor mechanism, the oculomotor centers in the brain, the oculomotor nerve which supplies the sphincter pupillæ, or, finally, by a direct influence on this muscle.

That the dilatation brought about by atropin is not dependent on any action on the centers is shown by the fact that when instilled into one eye it causes dilatation of the corresponding pupil without affecting the other. Since after application to the eye the atropin would be able to reach the centers only by being absorbed, and carried there through the general circulation, as after any other method of exhibition, it would necessarily be carried equally to both centers, and we would get a bilateral instead of a unilateral widening of the pupil. Further, Claude Bernard has found the mydriasis to occur in animals after section of the oculomotor, and H. C. Wood has seen it in man, both in cases of paralysis of the oculomotor nerve and of the sympathetic nerve, and, moreover, a number of observers have obtained dilatation of the pupil by atropin even when the eye has been completely removed from the orbit.

The drug, therefore, affects the pupil peripherally, that is, the dilatation is due to either an action on a portion of the nerve beyond the ganglia or else an effect

on the muscle. Bernstein and Dogiel found that electrical stimulation of the oculomotor nerve in cases of atropin mydriasis had no effect on the pupil, indicating again a peripheral palsy, but that when the electrodes were applied directly to the sphincter fibers of the iris the pupil was narrowed, showing that the muscle itself

had not lost the power of responding to stimulation. The dilatation, therefore, must be due to an action on the peripheral ends of the nerves.

The question as to whether the oculomotor nerve is paralyzed or the sympathetic stimulated is less easily answered. The fact that stimulation of the oculomotor fails to affect the atropinized pupil shows that this nerve is paralyzed; but whether or not the sympathetic is at the same time stimulated is a matter of some dispute. The fact that stimulation of the sympathetic, either electrically or by means of other drugs, such as cocain, is able to still more widely dilate the atropinized pupil, is brought forward as evidence that the sympathetic fibers are not stimulated by the drug. This, however, is by no means positive proof, for it is perfectly plausible to suppose that although atropin might have a stimulating effect on the sympathetic fibers, other measures could cause a still greater stimulation of these same fibers. It would be as logical to reason that because the combination of strychnin and atropin gives a greater increase in the respiratory movement than atropin alone that therefore atropin does not stimulate the respiratory center, as to reason that the sympathetic is not affected by atropin on the evidence given above.

Clinical experience in cases of adhesions within the eye shows that the dilatation of the pupil which occurs under atropin is more than a merely passive one, because it has force enough to frequently break up these adhesions. More than this, it has been found that when the eye has been completely separated from the body atropin is capable of causing dilatation of the pupil; and since in the removal of the eye the oculomotor nerve is entirely destroyed the further dilatation must be due either to a stimulation of the sympathetic terminals or a selective action on the radial muscles of the iris, which action is extremely improbable. We must conclude, therefore, that atropin dilates the pupil by paralyzing the peripheral end of the oculomotor nerve, and at the same time stimulating the terminations of the sympathetic.

Spinal Cord.—The effect of atropin on the higher nerve centers is a very complex one, and understood but very imperfectly. In the first place, every one knows that a large dose of atropin has some peculiar action on the brain, causing a wild delirium. Our knowledge of the brain, however, is not sufficient to allow us to determine more exactly the causes of this delirium.

Coming to the spinal changes, we note that although we find several theories to explain the effects of atropin on the spinal cord, our information is, after all, hardly definite enough to be called knowledge. To dismiss the question, as does one prominent text-book, with the remark that atropin affects the spinal cord like strychnin, not only avoids a perplexing problem, but is also a very inaccurate statement, for although there is, under the influence of atropin in the lower animals, a secondary stimulation of the spinal cord, more or less resembling a mild case of strychnin poisoning, the primary action of this drug on the reflex centers is widely different from that of strychnin. As was first discovered by Fraser, this early excitation is followed in the frog by a palsy so complete that in his earlier experiments Fraser thought the animal dead. Later, however, he showed that there was not only a return, but even a very distinct excitation of the reflexes. In other words, that atropin causes the following sequence of events: lessening of reflex activity, followed by paralysis, and followed again by excitement. Since pharmacology gives no instance of a drug which produces an exaltation of function after a primary depression, it is evident that atropin affects something more than merely the motor cells in the spinal cord. Fraser explained the series of phenomena by supposing that the spinal cord was excited from the beginning, but that in the early stage there was a paralysis of the motor nerves which prevented any impulses reaching the muscles; and that this paralysis of the motor nerves passed off more rapidly than the stimulation of the spinal cord, causing the appearance of the symptoms of excitation. Although it is true that a sufficient dose of atropin will paralyze the motor nerves in a frog, Ringer and Murrell have shown that protecting the nerve from the action of the poison by ligating the artery supplying it does not prevent the development of the paralysis, and that consequently the palsy is not dependent on any action either on the nerve or muscle. Moreover, in my own experiments, I have found that the time consumed in the spinal cord for the fulfilment of the reflex act is distinctly prolonged by atropin, indicating a lessening in the functional activity in the spinal centers.

The most plausible explanation of this peculiar sequence of events is that based on the supposition of the existence of a spinal inhibitory center. Of course, this is no time to discuss the truth or falsity of Setschenow's theory of spinal inhibition; suffice it to say that there are a number of pharmacologic facts inexplicable on any other hypothesis. We know that atropin paralyzes inhibition in the heart, and we know that atropin paralyzes inhibition in the intestinal tract, and it is only reasonable to suppose that it might also paralyze spinal inhibition. With the acceptance of this theory the explanation of the spinal action of atropin becomes a matter of comparative simplicity: there is first a paralysis of the spinal cord and also a paralysis of Setschenow's inhibitory centers. The paralysis of the motor cells does not last as long as the inhibitory depression, so that as the reflex centers of the cord regain their power the normal restraint is lacking and we have as the result a combination of abnormally exaggerated reflexes with muscular weakness.

Circulation.—The effect of atropin on the circulation is so well known that I shall dismiss it with but a few words.

Under the influence of the moderate dose of atropin there is a marked elevation of the blood pressure, accompanied by a very pronounced increase in the frequency of the pulse. The rise of blood pressure is due certainly in part to the increased heart action resulting from vagal palsy, but chiefly perhaps to the narrowing of the blood vessels. This is demonstrated by the fact that after previous section of the pneumogastric nerve atropin is capable of still elevating the blood pressure; and since after section of these nerves atropin has no effect on the pulse rate, the rise must be due to vasomotor stimulation. Furthermore, it has been shown that the drug is incapable of causing any considerable rise in the pressure after section of the spinal cord, that is, after destruction of the vasomotor centers; proof positive that the drug has a direct stimulating influence on the centers in the medulla controlling the blood vessels.

The increase in the work of the heart is due chiefly to the excessive rapidity of the pulse, which is dependent on removal of inhibitory restraint. That the

increased rate of the pulse is due to paralysis of the pneumogastric nerve is clearly proven by three facts: First, in those animals whose pneumogastric nerves are not in a state of tonic activity, as the rabbit, for example, atropin has little effect on the pulse rate; second, in those animals which, like man, have active inhibition, if the pneumogastric nerve is divided atropin is incapable of causing any distinct increase in the rate of the pulse; and, finally, electrical stimulation of the atropinized vagus does not slow the pulse.

It is probable, however, that the minute dose of atropin has a certain amount of stimulant influence directly on the cardiac muscle, for Beyer has found that the isolated heart of the terrapin is stimulated by small quantities of the alkaloid, and Langendorff brings evidence to show a similar effect on the frog's heart.

With this very cursory glance at some of the more prominent points concerning the physiologic action of atropin and hyoscyamin, we pass to the consideration of our second group.

HYOSCIN AND SCOPOLAMIN.

When we start to discuss the physiologic action of hyoscin, or rather before we start, we open a question on which there is so much disagreement that we can hardly claim to have any definite knowledge; indeed, even the existence of hyoscin is frequently denied, it being by many authorities considered to be identical with scopolamin. There seems to be but little doubt that in the majority of cases the substance sold under the name of hyoscin is in reality scopolamin; and there is certainly justification for the German Pharmacopeia in substituting for the name hyoscin the term scopolamin. Nevertheless, I am one of those who believe that there are two solanaceous alkaloids similar in their physiologic effects, and yet different enough to allow distinction, which have been known under the names of hyoscin and scopolamin. Both substances have, unfortunately, been called hyoscin, and as the true hyoscin seems not at present to be extant in commerce, what is to-day employed under the name of hyoscin is in reality scopolamin.

It is noteworthy in this connection that when Schmidt first asserted the identity of commercial hyoscin with the alkaloid scopolamin, he did not deny that the substance described by Landenberg might have been something else, and it is certainly taking a great many liberties with the work of an authority so well known as Landenberg to assert that his descriptions, both of the formula and of the properties of his discovery, were incorrect. There is both chemical and physiologic evidence of the separate identity of these two alkaloids.

Hesse has shown that certain specimens of scopolamin contain a substance with an optical rotary power muscle inferior to that of scopolamin itself. Louis Merck has brought confirmatory evidence to this discovery of Hesse's, in that he found that whereas the hyoscin prepared from hyoscyamus had an optical rotary power of 25 degrees, that from *Scopolia atropoides* had at times as low as 13.5 degrees; suggesting that in one or the other of them there was some other alkaloid which changed the effect of this substance on the rays of light.

Leaving out the chemical evidence we find that the physiologic evidence that there are two narcotic alkaloids belonging to the tropin series is sufficiently convincing. As far as I have been able to find, there have been but three careful complete researches on the action of hyoscin: those of Clausen, of Kobert and of H. C. Wood. All of these authors are in accord that hyoscin differs distinctly from atropin. For example, they all agree that it is not an excitant to the spinal cord; they agree that it is a somnifacient, although they are not unanimous concerning the power of its hypnotic action. It is interesting, however, to find that whereas the earlier researches, those of Clausen and Wood, showed throughout a fair degree of similarity, the later researches of Kobert differ quite widely from them in many respects. Thus, Clausen and Wood both found that the pulse was slowed by hyoscin in marked contrast to the effect of atropin; but Kobert, with full knowledge of the results of these investigators, and presumably exercising therefore even more than ordinary care, found that hyoscin affected the pulse precisely as did atropin, producing the same paralysis of terminal ends of the vagus. Moreover, whereas Wood found that comparatively small quantities of the alkaloid were distinctly depressant to the respiration, Kobert failed to obtain any lessening in the breathing, even with enormous doses. It is hardly possible that into the investigations of an experimenter of such ability as Professor Kobert, especially working as he did with knowledge of previous contrary results, there could have entered sufficient error to explain the differences of his results and those of the previous investigators; and it is equally illogical to suppose that the results of Clausen and Wood, one made in Europe and the other in America, at least one of the investigators being an acknowledged authority, would agree so closely in their results unless they had both been substantially correct. In the face of such contradiction the conclusion seems to me inevitable that Kobert had a different substance from that with which Wood and Clausen were working.

The clinical evidence of the separate identity of these two substances is also worthy of consideration. Both Wood and Kobert experimented on human beings concerning the effect of these substances on the brain; but whereas Kobert found that it was a comparatively feeble hypnotic, useful in only a minority of cases, Wood came to the conclusion that it was a hypnotic of considerable power. Every physician who has used hyoscin to any extent has noticed a very marked irregularity in its somnifacient action. At times it will seem to deserve a place among our most certain narcotics; on other occasions it will produce a condition more closely allied to the atropin delirium than to sleep. I myself believe that these differences can be most easily explained by the supposition that we are dealing with different substances.

In view of our ignorance concerning the identity of hyoscin and the dispute concerning its physiologic action, it is hardly possible to give in detail the physiologic action of hyoscin. In order, however, to consider the question of the action of mydriatic alkaloids in all its bearings, I shall very briefly point out the differences between atropin on the one hand and hyoscin as described by Wood and hyoscin as described by Kobert on the other.

It will be remembered that atropin is a powerful vasomotor stimulant; hyoscin, on the other hand, according to both the authorities quoted, exercises at no time any stimulant effect on the blood pressure. According to Kobert even enormous quantities have absolutely no effect on the blood pressure; but according to Wood, if the dose is large enough there is some weakening of the vasomotor centers. On the pulse rate Wood has found that hyoscin has not a great deal of effect, but tends somewhat to slow the pulse. On the other

hand, Kobert has found that the alkaloid overcomes the inhibitory stimulation of muscarin, and produces in the dog and in man an atropin-like paralysis of inhibition with consequent rapidity of the pulse.

Another difference between the actions of atropin and hyoscin is in their effect on the higher nerve centers. All authorities agree that under hyoscin there is lacking the primary stimulant influence of the central nervous system characteristic of atropin. According to Kobert, with the exception of the brain, hyoscin has no effect on the nervous system. On the other hand, Wood has found that hyoscin is distinctly depressant, not only to the brain, but also to the respiratory centers and to the motor side of the spinal cord.

In this very brief summary of some of the more vital points concerning the pharmacologic relations of the solanaceous alkaloids I have endeavored to present as fairly as possible the true state of our information, not attempting to hide our ignorance under the cloak of any unproven theory however ingenious and attractive it may be. It is painfully evident that there are many gaps in our knowledge of these principles; gaps which unfortunately limit their usefulness as practical remedies. The helplessness of the clinician to supply this lack in our knowledge is but another evidence of the value to practical medicine of scientific research. Until the scientist shall have demonstrated beyond cavil the chemical identity and the physiologic properties of these alkaloids, the practical physician, unable to know certainly what he is giving, can not expect to obtain definite therapeutic results from their use. And yet, many of these alkaloids seem to possess virtues which would make them extremely valuable to the physician if more clearly understood, and there is to-day as urgent need of careful scientific study of the mydriatic alkaloids as perhaps of any other group of drugs which are employed for the purpose of alleviating human suffering.

THE MYDRIATIC DRUGS AND THEIR ACTIVE PRINCIPLES.

THE OPHTHALMOLOGIC RELATIONS.*

CHARLES A. OLIVER, A.M., M.D.
PHILADELPHIA.

The drugs spoken of as mydriatics are ophthalmologically divisible into four classes—analgesics, mydriatics, iridoplegics and cycloplegics. They receive their generic name from the most prominent objective sign that is produced by their action. By reason of their many-sided effects they are the most valuable diagnostic and therapeutic agents which are employed in ophthalmic practice, the effects being mainly dependent on varying grades of true peripheral palsy.

They always act locally. This has been proven by the application of mydriatic-containing aqueous humors to other eyes, and by the action of the drugs after excision of the heart, after decapitation and after isolation of the eyeball. Further proof of their local action is shown by their increased activity after removal of the external layers of the cornea. Moreover, local applications never affect the fellow organ in a similar way.

Most prominent among the mydriatic agents are: holocain, cocain, eucain, euphthalmin, homatropin, mydrin, atropin, scopolamin, daturin, hyoscyamin, hyoscin and duboisin.[1] As is well known, many of these alkaloids, although differing by but one or two elemental atoms each, or even when absolutely isomeric, have variable physiologic actions on one and the same series of ocular structures. So, too, with the supposedly identical alkaloids derived from the same genus of plants grown in various countries, under varying conditions, or when obtained from one and the same plant at different ages. These peculiarities of action are probably dependent on idiosyncrasies of molecular arrangement of the same number of contained elements, the relative optimal and subinvolutional conditions of the contained cell-forms, and the variability of the ocular structures.

The only true method of differentiating these effects and grading the relative degrees of therapeutic usefulness of the drugs is to study their comparative powers on the excessively rare normal emmetropic eye or on the carefully corrected and healthy ametropic organ; a plan which gives a series of known factors on which to base desired effects on irritated, inflamed, and at times, weakened tissues.[2]

The chief effects of this class of therapeutic agents on the eye consist in external and internal analgesias combined with local paralyses of the sphincter muscles of the iris and ciliary body. By some observers most of the drugs (particularly atropin, daturin, scopolamin, hyoscyamin and duboisin) are supposed to exert simultaneous excitatory actions on the radiary fibers of the iris and the ciliary body. Some of the drugs are said to contract the blood vessels and to act on the peripheral ends of the nerves. A number of authorities believe that cocain-, holocain- and eucain-mydriases are due to local irritation of the sympathetic nerve endings in the iris (both vasoconstrictor and pupil-inhibitory fibers).

The local effects of the drugs are increased by bodily rest, with non-usage and non-exposure of the ocular organs. Cold applications diminish both the primary and secondary actions of the drugs. Heat tends to promote both of these results.

While the drugs are in use, colored glasses—preferably smoke-tinted coquilles which are free from blemishes and optical imperfections—should be worn. The degree of tinting should be regulated by the feelings of the patient and the conditions of the case. All of the solutions should be freshly prepared in small quantities, made neutral and kept only for brief periods of time. Some ophthalmologists prefer to add boric acid or some preservative to the solutions, but this is not necessary if the above rules are followed. During the instillation of the drugs care should be taken to prevent their passage into the lacrymal and the nasal passages.

The drugs which are employed for the definite and determinate purpose of pure mydriasis in ophthalmology are comparatively few. In the writer's hands they are limited in the order of their relative values to the following: euphthalmin, homatropin, mydrin and ephedrin. Used in the strict sense of the term they serve an im-

---

* This abstract of the original paper, read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, is approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

1. Several other less frequently employed alkaloids, delphinin, solanin, etc., are not considered here. A number of experiments with the biborate and the salicylate of solanin have been conducted by the writer, but the results are reserved for a paper on another subject. The writer has not considered drugs, such as gelseminin, coninin, aconitin, which produce local effects on the eyeballs and their related structures by ingestion and topical application elsewhere, even when they are thus intended: for example, the internal administration of hyoscyamin for spastic conditions of the interior and exterior ocular muscles. Such drugs as strychnin and curare also have not been considered.

2. In the tests which have been conducted by the writer similar conditions in regard to illumination, time of day, condition of eyes, form of apparatus, and choice and use of drugs have been maintained.

portant purpose by permitting a broader view of the interior of the eye.

Euphthalmin is usually employed in the form of the hydrochlorate. Two drops of a 5 per cent. strength solution produce almost a maximal mydriasis, which lasts some two or three hours, and which is maintained under strong light stimuli, the pupil returning to its normal size in from twenty to twenty-two hours' time. The action of the drug on the ciliary muscle is very slight, a similar amount of the same strength solution evidencing its primary weakening influences on the power of accommodation in from ten to fifteen minutes' time, the maximum effect being reached in sixty to eighty minutes, and the last remnants of action not ceasing until five to seven hours have elapsed.

The drug is the best agent which we possess for pupillary dilation for ophthalmoscopic diagnosis. It is more powerful than mydrin. It is slower than homatropin in its action, yet its effects pass away more quickly, and it neither degenerates the corneal epithelium nor possesses any irritative or general intoxicant effects.

Homatropin, a mandelic ether of tropin, is generally used in the form of the hydrobromate. It is prepared synthetically. In 2 per cent. strength solutions it is used as a mydriatic. (In greater strengths, or by repeated instillations, it is employed by many as a cycloplegic for the estimation of refraction. For this purpose many ophthalmologists instill two drops of a 1 to 4 per cent. strength solution into the conjunctival sac every five or ten minutes until three or four instillations have been made, examining the eye for lenses in thirty minutes' time after the last instillation. These strengths of the drug employed in this manner will produce palsy of the ciliary muscle which will last at least sixty to ninety minutes, recovery usually taking place in about forty-eight hours' time.)

For mydriatic purposes, one drop of 1 to 500 strength solution instilled into the conjunctival sac every five minutes until five instillations have been made will produce a maximum effect of dilation on the pupillary area in from three-quarters of an hour to an hour's time, the pupil commencing to dilate in from six to fifteen minutes and returning to its normal size in about fourteen to eighteen hours' time.

(Its effect on the iris and the ciliary muscle is increased by the addition of cocain. This can be accomplished by placing one-fiftieth of a grain each of the two drugs in discs which are allowed slowly to melt on the conjunctival surface, and from thence to be absorbed into the interior of the organ. Oleaginous menstrua and oily excipients hold the drug in position for a longer time and thus increase the amount which is absorbed into the interior of the eyeball.)

In some cases, the mydriasis produced by this drug will partially disappear temporarily when the subject is placed under the influence of a general anesthetic.

Mydrin is an artificial preparation composed of one part of homatropin hydrochlorate to one hundred parts of ephedrin in a 10 per cent. strength aqueous solution. Applied to the conjunctiva the pupil begins to enlarge in from six to ten minutes' time, dilating to a maximal size of some 4 to 7 millimeters in about thirty to thirty-five minutes. Twenty to twenty-five minutes later the enlarged pupil begins slowly to diminish in area until in from four to six hours' time all artificial mydriasis has disappeared. This mixture is much more effective as a mydriatic agent than either of its constituents in their uncombined proportions. Powerful light stimuli, forced accommodation and strong convergence impulses either exerted separately or in association will give rise to iris-play with slight pupillary contraction. (The belief that the drug does not exert any paretic action on the ciliary muscle is untrue. Repeated experiments in regard to this question by the writer have conclusively shown the loss of one, and even of two, diopters of accommodative power gradually taking place in about eighteen to twenty minutes and passing away slowly in from six to eight hours' time.)

Such a drug, therefore, is useful for mydriasis of brief duration, rendering it valuable as an adjuvant for diagnostic purposes.

Ephedrin is an alkaloid which is derived from *Ephedra vulgaris.* One or two drops of a 2 per cent. strength solution will give rise to almost complete mydriasis in an unirritated and healthy eye in about fifty minutes' time. (The action on the iris can be noticed in about eight minutes and lasts for eleven or twelve hours. There is a very slight effect on the ciliary muscle, and, as a rule, there is not any increase of intraocular tension.)

The writer has successfully and usefully employed this drug in weak solutions for partial pupillary dilation for diagnostic purposes. In a series of unpublished experiments with single instillations of the one-hundred-and-twentieth, the one-sixtieth, the one-fortieth, the one-thirtieth, the one-tenth and the one-fifth of a grain of the hydrochlorate salt, he has found both corneal and conjunctival analgesia preceded by slight hyperemia with the stronger percentages, and irregular pupillary dilation (from four to five millimeters with the weaker strengths, and from seven to eight millimeters with the stronger ones); all appearing in ten to fifteen minutes and lasting from twenty to thirty hours. With most of these amounts there was a series of definite recessions of the near-point, these being obtained at periods averaging thirty to forty minutes after the use of the drug. No general symptoms, except an increase of the pulse-rate in a few minutes and a slight frontal headache in a case or two could be noticed.

In combination with homatropin the drug acts more rapidly and with increased energy.

DISCUSSION

ON THE PAPERS OF DRS. LYONS, WOOD AND OLIVER.

DR. A. W. BAER, Chicago—I regret that the members of the Section on Ophthalmology could not have been present to hear these papers. I do not know any other class of drugs which are used as commonly and as indiscriminately as the mydriatics, or which, when carelessly used, are capable of leaving such bad effects. I can recall cases in which mydriatics have been used to dilate the pupils, and I do not believe that the patients have ever regained the full use of their ciliary muscles. Atropin acts directly on the neuron and alters its condition so as to produce paralysis, which, at least to some degree, may be permanent. I hope that this point will be brought out more fully in the remarks of other speakers who have more experience in this class of drugs.

DR. W. J. ROBINSON, New York—There can be no question with regard to the occasional bad effects following the use of mydriatics. This may be accounted for by the bacterial contamination, or infection, of the stock solutions which physicians keep in their offices. This is not merely a theoretical assumption, but has been made the subject of positive demonstration. Many practical suggestions have been made in order to prevent this contamination. For instance, boric acid has been used, a few grains being added to the stock solution; but it is not always desirable or suitable and, besides, its antiseptic power is slight. Many other antiseptics have also been tried. I think the preferable plan is to make the stock solution with

45 per cent. alcohol, for in this medium the alkaloids will keep very well. Other solutions of any desired strength can be made extemporaneously, by adding recently boiled distilled water. In the *Correspondenz-Blatt fuer Schweizer Aerzte*, there recently appeared a very complete review of this subject, in which the writer, after considering the various methods which had been proposed, spoke approvingly of this solution with alcohol (45 per cent.). In it the alkaloids do not undergo any change. Some of the stock solutions have been kept as long as seven months, and have shown no signs of decomposition or alteration.

DR. A. B. LYONS—The last paper illustrates what I attempted to show, that in prescribing these articles by their names, atropin, hyoscyamin, digitalin, hyoscin, scopolamin, etc., it is necessary to consult first with the chemist in order to ascertain what these articles really are, and whether they consist of the pure alkaloids, or whether they are a mixture of several principles and, if so, in what proportion. If it is found that they contain only one alkaloid, we must find out just which one it is; atropin, hyoscyamin, hyoscin, etc. These are among the most variable of substances known to the chemist. Unfortunately, unless special care be taken, the experimenter with these drugs will be in this precise predicament. He buys an article, like scopolamin, for instance, and he gets commercial "scopolamin" and not what the chemist would call by that name. In the same way the physician may prescribe one of these alkaloids for his patient, to be compounded in a capsule, but, after doing so, he is not in a position to say exactly what was really used in making that capsule, or what its effects should be on his patient.

DR. H. C. WOOD, JR.—I wish to emphasize the remark just made by Dr. Lyon, that in prescribing this class of drugs we do not know exactly what we are using. Physicians very commonly use the solanaceous plants, but I am sure that frequently they do not know precisely what they are giving to their patients even when they order the alkaloids. Dr. Robinson has spoken about sterilizing the solutions in order to ensure the permanency of the drug. This is a very necessary procedure. I had a very instructive experience illustrating this point. I had a bottle of atropin, obtained from one of the most reliable houses in Philadelphia, and from it I made solutions for use in experiments. Not having occasion to use it for several months, it remained unopened on the shelf, until I had occasion to make some control experiments with atropin. I made a fresh 2 per cent. solution and injected an ordinary dose into a dog, but got no characteristic effect, even after greatly increasing the dose, beyond dilatation of the pupil. I made a fresh solution, with the same negative result; I could get no atropin reaction whatever. I concluded that the drug had undergone some change, probably from bacterial action, although the bottle had been tightly corked. The contents of the bottle had become completely changed without giving any evidence to the eye. The same change may occur in the stock of the druggist. Therefore, I have very little confidence in supplies from the ordinary druggist and I do not think that we get exactly what we ask for when we prescribe these mydriatic alkaloids. If we ask for scopolamin, we may get hyoscin; if we ask for hyoscin, we may get scopolamin or hyoscyamin.

The Importance of the Prognosis.—The late Professor Gerhardt of Berlin used to say "the prognosis is the highest and ultimate achievement in the art of medicine as it presupposes everything else. The prognosis is based not only on knowledge but also on skill made possible by natural gifts and acquired by experience. It also has to take into account the sum of the personal properties of the patient, usually styled the 'resisting power.' This is the point in which the experienced family physician frequently surpasses the learned specialist. How differently, for example, is pain borne by different persons, bravely and unflinchingly by one, with an agonal expression by another. When the physician is certain of his prognosis, courage to proclaim it should come with it. It is easy to avoid mistakes by saying nothing. He who does not shoot at all will not miss the mark. But neither will he ever become an expert marksman."

THE EARLY APPEARANCES, DIAGNOSIS AND TREATMENT OF TUBERCULOSIS OF THE UPPER AIR TRACT.*

WALTER F. CHAPPELL, M.D.
M.R.C.S. Eng.; Surgeon, Manhattan Eye, Ear and Throat Hospital.
NEW YORK CITY.

The subject embraced in the title of this paper is really too important to be fully considered during the time at my disposal, and can therefore only be treated briefly from a somewhat personal standpoint. At one time I thought any one who had ordinary opportunities of studying tubercular manifestations on mucous surfaces could have little difficulty in recognizing their appearance in the upper air tract. Some mistakes on my part, and a wider experience in this branch of our special work, have changed the views I formerly held, and I now consider it most difficult and I might almost say impossible to arrive at a correct diagnosis in certain cases. Of course, this does not refer to patients who have all the typical, local and general symptoms, but rather to those where they are absent and the conditions simulate some other affection. No part of the respiratory tract is immune from tuberculosis, but certain points in the upper air passages seem more liable than others. These in order of frequency are the larynx, pharynx, trachea, tongue and nasal chambers. If time permitted it would be most interesting and instructive to consider what determines the special localities, and by what means the infection is conveyed. We can not stop for this now, and must hasten on to the text of the paper.

THE THREE STAGES OF THE DISEASE.

We have to make a diagnosis at three distinct stages of this disease as it occurs in the larynx.

1. The premonitory or pretubercular stage.
2. The stage of infiltration or thickening.
3. The stage of ulceration.

Is there a premonitory stage, and can we recognize it? I certainly believe that more or less definite symptoms precede every local deposit of tubercle in the larynx, but as they are not pathognomonic they can not be depended on. Many catarrhal inflammations have a close relation with tuberculosis on mucous surfaces, but it is often difficult to determine whether they are cause or effect. I have frequently seen a profuse and intractable laryngeal catarrh or laryngorrhea continue for several months in a tubercular patient before there were any definite symptoms observable in the larynx. Local pallors have for years been named in text-books as an early sign of tuberculosis. I can not agree with this statement, as the majority of my cases did not present this condition. In a great number of cases of pulmonary tuberculosis, which I have had an opportunity of observing in private practice and at the Loomis Sanitarium in Liberty, the mucous membrane of the soft palate, larynx and pharynx was extremely pale. This condition remained to my personal knowledge from two to six years without any deposit in the upper air tract. We would naturally think that impaired nutrition, local anemias or catarrhal inflammations of a mucous membrane would make it more susceptible to any infections, but I do not believe that any of these conditions alone or combined would determine a tubercular infection, but that a personal equation must always be considered. Recurring and persisting hyperemias, infiltrations and

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

tumefactions are, in the writer's experience, the most usual and characteristic signs of early laryngeal tuberculosis. They appear as patches or may involve the whole interior of the larynx. The interarytenoid space, ventricular bands, posterior third of vocal cords and epiglottis are the usual places for early circumscribed infections. Any of the enumerated symptoms, occurring in the situations described, should cause some anxiety and a careful watching of their progress, and especially so if pulmonary tuberculosis already existed. These symptoms may be present, however, without being tubercular even in a tuberculous patient. Cold, rheumatism and voice strain will produce laryngeal redness and thickening, which may continue at intervals for years.

One of my patients, a lady, had an acute interarytenoid folliculitis every winter, and occasionally during the summer, for ten years to my personal knowledge. It was accompanied by great local thickening of the mucous membrane and some edema over the arytenoid bodies. During several unusual severe attacks small strips of ulceration appeared, but healed after the acute symptoms subsided. For several years I feared a tubercular infection, and other physicians who saw the case expressed the same opinion. As time passed these fears proved unfounded, and I constantly see this lady in perfect health, other than occasionally suffering from the attacks described.

Another case, showing the difficulty which often confronts us, is that of a Mr. G., who consulted me for a hoarseness he had had for three months. He caught cold and became hoarse for the first time in his life, and although the other symptoms of cold subsided the hoarseness continued. I found him a fine specimen of manhood, with a perfect family and personal history. The mucous membrane of the interior of the larynx was a brick red color, slightly paler over the vocal cords and possibly a little thickening of the ventricular bands.

From the history and in the absence of any chest symptoms and negative sputa reports I consider the case one of neglected laryngitis. He remained under my treatment for about three months, with some improvement, and as summer arrived I sent him to the mountains. He returned to the city in September with more hoarseness, considerable cough and slight rise of temperature and pulse and a loss in weight of four pounds. The mucous membrane of the larynx was much redder and more thickened, especially in the center of the right ventricular bands and had the appearance of a tubercular larynx, although no bacilli were found, and the examinations of the chest were negative. A month later he had a profuse tracheal and bronchial catarrh and a few bacilli were found in the sputa and urine. From this time the disease made rapid progress, and six months later the patient died of laryngeal, pulmonary and renal tuberculosis.

If clinical facts and ordinary skilled observations can be depended on, it does seem that this infection primarily occurred in the larynx, and the first symptoms observable were general redness and tumefaction. Small papillomatoid excrescences in the interarytenoid space are considered by some as pathognomonic of tuberculosis. This belief is erroneous, as I have frequently seen a similar condition in syphilis and chronic laryngitis. A greyish appearance in the posterior commissure is also very puzzling at times. It may result from a thin tenacious mucus covering the surface, or a smooth fibrous-looking membrane resulting from voice strain or a superficial tuberculous deposit. The latter has a decided edematous appearance, the papillæ in the arytenoid space stand up as small pyramids covered with a mantle of grey. Small ulcerations soon develop between the papillæ, but as time progresses and the periods of activity and quiescence occur, larger ulcers form. In some cases efforts at repair produce excessive granulation tissue, which at times become so large as to be designated as tubercular tumors. The nature of these masses are difficult to determine when seen for the first time, but, if tubercular, there is always a history of pulmonary and laryngeal diseases, extending over some years.

STAGE OF EDEMA AND ULCERATION.

An edematous or semi-solid appearance of the mucous membrane is usually a precursor of tubercular ulceration, especially when it occurs over the arytenoid cartilages, ary-epiglottic folds and epiglottis, and at times the swelling is so great as to seriously interfere with respiration and deglutition. Small points of ulceration soon follow and after coalescing give the so-called characteristic worm-eaten appearance. Superficial inspection, in my belief, is most likely to cause the described conditions. The single, large, deep tubercular ulcer is rather infrequent and occurs on the ventricular bands and in the arytenoid space, and results from a deep lymphatic infection. Syphilitic ulcers may occupy the same locations as tubercular ulcers, and at times it is difficult to distinguish them by their macroscopic appearance. As a rule the syphilitic ulcer is large, although it may be small and multiple in the secondary stage. It spreads rapidly and appears more quickly after the first laryngeal symptoms. That is to say, there may be a history of hoarseness for a few days only and on examination a large ulcer is found.

In tuberculous ulceration there is always a long history of hoarseness or pain with other laryngeal symptoms running a chronic course. Pain is an important diagnostic symptom and I do not believe much tubercular ulceration can occur without pain on swallowing. On the contrary, a very large syphilitic ulcer may be present without pain. The characteristic appearance of a tubercular ulcer will be described later on, as the opportunities for observing it are better in the pharynx.

PHARYNGEAL TUBERCULOSIS.

The pharynx, in my experience, is the next frequent location for tubercular invasion. Time will not permit me to discuss the so-called latent tuberculosis of the tonsil, and I will confine my remarks to observations of parts giving the usual clinical symptoms. The pharyngeal infections are usually secondary to pulmonary and laryngeal tuberculosis.

I have seen a number of such cases pass upward along the lateral pharyngeal folds from the larynx and rapidly invade the pillars of the fauces and soft palate, and in many instances the lymphoid tissue at the base of the tongue.

I have several times had the opportunity of watching these cases from the beginning to their termination and the process of invasion is very interesting. The mucous membrane has first a pearly grey tense appearance, but within forty-eight hours is covered with minute yellow spots, such as seen in Figure 1. At first these spots had a thin covering of epithelium, but within twelve hours this broke down and bright yellow, curdy-looking secretion dotted the surface. This was easily brushed away, leaving extremely small openings plugged with yellow secretions. As soon as this secretion appeared the mucous membrane lost its tense edematous appearance. Within a week the small ulcerations coalesce, leaving large irregular ulcerating surfaces. A case

of primary pharyngeal tuberculosis[1] was of great interest and the local conditions are well demonstrated in Figure 2. This infection followed an operation for the removal of adenoids in a girl of 19 years of age, and proved rapidly fatal. Within a year another case has come to my attention, which had many remarkable features, and seemed to have primarily started in the pharynx. Later, however, it was discovered that the kidneys were the seat of a tuberculous process. This, of course, raised the question of the throat being secondary to the renal infection.

This patient had a slight sore throat in August, 1901, which made its appearance as an unhealthy greyish-looking membrane, covering the left tonsil, and soon the right tonsil was also involved. A diagnosis of diphtheria and later syphilis was made. After six weeks the temperature began to rise, and the ulceration extended up on the left side to the soft palate. Tubercle bacilli were now present in great abundance. Several of the best known physicians in New York reported that their examination of his lungs revealed no disease. His death resulted from uremic coma, and emphasizes the

Fig. 1.—Secondary pharyngeal tuberculosis.

importance of a careful urinary examination in all tubercular cases.

TRACHEAL TUBERCULOSIS.

This is more often present than is generally supposed, and I have many times found a tracheal ulcer which had not been suspected. The difficulties surrounding a thorough examination of the trachea are very great and sometimes can not be overcome. Tubercular ulcers are usually found on the anterior wall of the trachea just below the vocal cords.

The symptoms produced are a constant burning or a tickling sensation, referred to this region, accompanied by a violent explosive cough. It is not unusual for ulcerations to attack the rings of the trachea, and in these instances small pieces of cartilage may be expelled by coughing. If the local manifestations can not be seen in the trachea the symptoms just described would make us reasonably sure of the diagnosis.

TUBERCULOSIS OF THE TONGUE.

It has been customary to state that lingual tuberculosis is rare, and this is true of primary infections, but does not apply to secondary cases. During the past six years I have seen fifteen cases of tuberculosis of the tongue, fourteen of which were secondary and one I believe primary. Much scepticism exists as to the possibility of a primary infection in any part of the upper air tract. I want, however, to go on record as a believer in the possibility of this occurrence.

A secondary lingual infection is usually a late manifestation of a laryngeal and pulmonary disease. It makes its first appearance as a small isolated greyish

Fig. 2.—Primary pharyngeal tuberculosis.

nodule in the situation of some previously recognized abrasion. This nodule soon breaks down into a painful ulcer, which appears flat and irregular in shape, or as a deep fissure. In either case there is no surrounding infiltration and the margins of the ulcer adhere closely to the underlying surface, and if separated the tubercular process will be seen to burrow beneath the mucous

Fig. 3.—Secondary tubercular fissures of the tongue.

membrane and in some instances to the extent of a fourth of an inch. This condition is well shown in Figure 3, and is a marked contrast to the lingual fissure in Figure 4. The latter is a representation of a syphilitic fissure in a patient who innocently contracted the primary sore on the lip. You will notice the entire absence of any burrowing character to these fissures.

The base of a tubercular ulcer can be carefully studied on the tongue, and we find it consists of a pearly grey glistening membrane, which is adherent closely to the

1. Reported in the New York Medical Journal, Sept. 19, 1896.

underlying tissues, and differs so entirely from other ulcerations that I believe it is characteristic of tuberculosis on mucous surfaces. The tubercular fissures cause a great deal of pain, which is more or less intermittent, depending on the activity or quiescence of the disease. Figure 5 represents what the writer believes to be an instance of primary invasion on the tongue.

Mr. D., age 30, had no family history of tuberculosis and descended from an exceptionally strong and sturdy family, and his personal history was also good. Four years previous to my seeing him he was under the care of a dentist, for about ten days, having his left upper molar prepared for filling. Two marginal points of the tooth were exposed and were very sharp during this time, and Mr. D. was in the habit of touching the points with the tip of his tongue. The latter soon became sore, and an examination showed a red elevation with a fissure on its surface. This gradually increased in size, and some two weeks later the surrounding mucous membrane became puffy and the fissure gradually enlarged and presented a small, painful ulcerated surface. Medical advice was sought, and various applications were recommended and employed for a year or more. During this time the ulcer spread and embraced the entire tip of the tongue, chiefly on the right side. His general health remained good and he continued at his usual business.

Fig. 4.—Secondary syphilitic fissures of the tongue.

The tongue, however, became so painful that he consulted a surgeon, who removed a piece of tissue embracing the ulcerated surface. Microscopic examination revealed the presence of tubercle bacilli. The day following the operation Mr. D. noticed a small white spot on the mucous membrane near the former ulcer. The cut surface of the lingual wound granulated, but the margins did not adhere. Two months after the operation the small white spot already referred to became an ulcer, and gradually spread until in eight months it extended over the entire surface of the original operation. Four months later his voice became husky, owing to infiltrations in both arytenoid cartilages and the interarytenoid space, and he could speak only in a whisper. It was two years after the tongue affection before any pulmonary disease was discovered, but at no time was this extensive.

NASAL TUBERCULOSIS.

A tubercular ulceration on the anterior part of the triangular cartilage of the septum is by no means rare, but I have only observed two cases in other parts of the nasal chambers. The infection is very slow in progress and produces few, if any, symptoms which would point to the presence of an ulceration. A perforation is often the first evidence we have of its presence.

MEDICINAL TREATMENT.

The pessimistic views of some writers seem hardly justified in the light of our present results. Personally I believe that a great deal can be done for these cases if we are willing to give the necessary thought and attention to each individual patient, and not treat them all as a class to receive one line of treatment. I will not repeat the remedies and methods recommended by other observers, but confine my remarks to personal experiences. For clearness we may divide the treatment into medicinal, surgical and climatic.

Fig. 5.—Primary tuberculosis of the tongue.

In the early stages, when only redness of the larynx exists, soothing sprays and warm inhalations, followed by mild astringents, should be employed. When congestion is combined with thickening a spray of adrenalin should be added to the treatment, and in marked cases of thickening submucous injection of lactic acid or creosote may be used. These injections should be given only during the quiescent stage and not while there is any temperature, indicating pulmonary or laryngeal activity. In ulcerative conditions I strongly urge that no irritative applications be used during any active process, but rely entirely on soothing and cleansing sprays and applications of iodoform and fluid benzoin. As a warm inhalation the following:

℞. Iodoform ..... grs. iv
Menthol ..... grs. iv
Chloral hyd. ..... grs. iv
Fluid benzoin ..... ʒi

The benzoin preparations are of special value for applications in the larynx, as they cling to the mucous membrane for hours and keep the medication in con-

tact. During an interval of quiescence the ulcerations may be treated more actively with 25 per cent. solution of lactic acid, or the No. 2 creosote solution recommended by me. This latter solution certainly relieves pain more successfully than lactic acid, but regarding their relative effect on tubercular tissue there is little choice. The granulation tissue which appears on ulcerating surfaces during the process of repair has to be protected and stimulated in the most careful manner. I know of nothing more useful in this purpose than nitrate of silver in weak solutions.

Pain is an important consideration and varies from a slight degree on swallowing to a continuous and intense suffering. Warm inhalation of menthol and iodoform are sufficient for the slight cases, but cocain, orthoform and creosote are necessary for those of greater severity. When the general soreness and aching of the larynx is not relieved by the remedies mentioned, application of cold should be used. This may be done by menthol, camphor and chloral hydrate in equal proportions, externally applied, or by the ice coil, bag or pack. In some cases we have to resort to internal medication to assist us in the relief of pain. The elixir of paraldehyde may be sufficient, but usually morphin or codein in some form is necessary.

SURGICAL MEASURES.

Any surgical treatment must be restricted to selected cases and for experienced operators. In my practice and also in that of my fellow workers I have seen considerable harm result from the indiscriminate use of the curette. A recent case greatly impressed this on me.

A Japanese with a tubercular infection involving the arytenoids and epiglottis consulted me, and, after learning the nature of his trouble, expressed a determination to return to his native country. The obstruction to respiration was so great that something had to be done immediately to relieve the dyspnea, and I used the curette, removing a quantity of thickened tissue. Within thirty-six hours the lateral pharyngeal mucous membrane puffed up and presented the characteristic swollen or grey edematous appearance of a tubercular invasion. Twenty-four hours later this spread to the left palate and lymphoid tissue at the base of the tongue.

If time permitted I could quote many similar instances. I now employ the curette only in the following conditions: To relieve dyspnea and dysphagia in advanced cases; to remove tumefied tissue and for scraping ulcers during a quiescent period. In the latter cases my plan differs slightly from that usually recommended. After cleansing and cocainizing the surface I use a dull curette to remove all the necrotic tissue, taking care not to cause any bleeding. After this has been done and the pearly grey floor of the ulcer thoroughly exposed, I apply such remedies as the necessity of the case indicates.

CLIMATIC TREATMENT.

I would rather take my chance with a good climate without special medical treatment than the best of treatment in a poor climate. Just what is the best climate is not easily decided. Residence near the sea or any large body of inland water or in large cities is a bad place for tubercular throats. In the early stages before ulceration or during the quiescent stage of ulceration a dry and cold atmosphere is beneficial. If the process in the larynx is in a stage of activity a moderate temperature is important. High winds, especially east and north, and damp foggy days are bad for all ulcerations, especially the active cases. As a rule all tubercular throats are better in a moderately warm, dry climate, free from dust and winds. I have seen a number of throat infections entirely arrested by climatic measures alone, but, of course, the permanency of any arrest must remain an open question. In my opinion the future of all arrested cases, either laryngeal or pulmonary, depends on an early diagnosis and the patient's financial ability and willingness to keep himself under climatic and hygienic surroundings suitable for his highest state of existence.

7 East Fifty-fifth Street.

DISCUSSION.

Dr. Emil Mayer, New York City—The importance of the early recognition of tuberculosis is a subject that is as near to us as any one subject that I know of. It comes to us in so many different ways. In a case that came under my observation the young man had a bad tubercular history, his father, mother, one brother and sister having died of tuberculosis, and the young man came to me feeling that he was going to have tuberculosis.

There was nothing to be seen in the pharynx, and yet he had attacks of laryngeal spasm. For my benefit he succeeded in having an attack in my office, and it was an alarming one. He had a slight deposit of lymph in the nose, which was examined carefully, but no tubercle bacilli were found. He was examined by one of our best medical men, but no evidence of any pulmonary trouble was found, and the diagnosis of no tuberculosis was made. With the exception of a short cough, these were the only symptoms he had. He was advised to go abroad for the benefit of his health. In three weeks time he went abroad, and an examination of his nose then showed tubercle bacilli. We have all of us seen interarytenoid thickening, which usually speaks for tuberculosis that will supervene in a comparatively short time. Shortly before coming here I saw a young man who appeared before me two years ago with an interarytenoid thickening which is still present, but I believe tuberculosis will eventually appear in those cases. One thing I would like to speak of is the use of cocain for the relief of pain. I believe, with the preparation of orthoform in powder, we can almost invariably stop the pain without cocain, and I am more impressed by that in that I have seen, within a fortnight, a woman in the last stages of tuberculosis who was advised to use cocain and got rest from its use. She gets only temporary relief, but she has developed now the cocain habit. I make that as a suggestion, and I think Dr. Chappell will agree with me that if we have other methods just as efficient and can avoid these drugs that will make the patients still more unhappy, it is an important consideration.

Dr. Clement Theisen, Albany, N. Y.—I do not know whether the Doctor spoke of the rare form of hypertrophic tuberculosis sometimes seen. I will briefly report a case that I saw about a year ago. A gentleman walked into my office one day, and the first thing that impressed me was his curious husky voice. I think the aphonia of laryngeal tuberculosis is different from the aphonia of anything else. He seemed to be otherwise in perfect health. Examination of the lungs was negative. On laryngoscopic examination I found absolutely nothing to indicate laryngeal tuberculosis. There was only a diffuse thickening over the cords and ventricular bands. I made a very careful examination of the larynx, and several examinations of the sputum were made, but nothing was found. I told him, however, that I was strongly inclined to think that he had laryngeal tuberculosis and that I thought his only chance was to go west. He started west, but for some reason returned to New York and was seen by a number of well-known laryngologists, who made different diagnoses. The case was reported by one gentleman as a case of diffuse pachydermia laryngis. Six or seven examinations of the sputum were made, which were negative, and nothing, I believe, was found in the lungs. In the Adirondacks he was seen by Dr. Trudeau, tubercle bacilli were found in the sputum, and he died about six weeks after going to

the woods. I believe it was a case of primary hypertrophic tuberculosis.

I used to curette my cases of tuberculosis when not too far advanced, but I have given that up, for I believe it is of service only in the earliest cases, when the tuberculous process first starts. When we remember that the tuberculosis begins in the deep tissues first and is, as a rule, secondary to pulmonary involvement, we can see that curettage is of doubtful value, for we can never be sure that we have removed all the tuberculous tissue. I agree with Dr. Mayer in regard to orthoform. I believe it will relieve the pain. I use it in the form of Frazer's tablets. I think the effect is much more lasting than from cocain, and there is no danger of acquiring a dangerous habit, although this danger need not be considered in the advanced cases.

Dr. F. J. Quinlan, New York City—The title of the paper is "The Early Appearance, Diagnosis and Treatment of Tuberculosis of the Upper Air Tract." It seems to me the Doctor has given us especially the treatment of the more advanced stages, when there is tumefaction and breaking down of tissue. I know nothing more perplexing than the early appearance of pharyngeal or buccal tuberculosis. If one were to be guided by the appearance without the subjective symptoms, I think he would narrow himself down to a small and limited field of symptoms. We should not be satisfied with the local appearance alone. When we have only a small degree of infiltration about the superficial structures, with hardly any evidence but a suggestive cough and slight huskiness as well as a little pain from time to time in deglutition, we are not justified in making a diagnosis without entertaining the range of subjective symptoms as well. I have never seen a case in which I felt satisfied as to early diagnosis, and I think we are handicapped without the consideration of these other subjective symptoms. I have known case after case in which there were no bacilli reported in the sputum and yet there was a tuberculosis. I think the pulse, temperature and respiration must always be a valuable adjunct to our means of diagnosis, as well as the repeated examination of the sputum. I am very much pleased that Dr. Chappell has given so much thought to this subject, but I hoped that he would emphasize more suggestive points as to the earlier appearances.

Dr. George C. Stout, Philadelphia—There were three features in the paper which especially appealed to me: First, the more favorable prognosis we may now give these cases, as compared with that of a few years ago, and this is more often true of course in the early stages. The second point is as to the relative importance of climate and local treatment; and the third is as to the use or disuse of instruments in ulcerative tubercular laryngitis.

In regard to prognosis, I would like to record a case seen three years ago. A woman, apparently about 30 years of age, presented herself at my office, having suffered with a severe cough for some months past, with emaciation, rise of temperature and the general symptoms of tuberculosis. The laryngeal appearance showed marked swelling of the left arytenoid region, there was a small interarytenoid ulceration, and tubercle bacilli were found in abundance in the sputum. A careful examination of the chest eliminated lung symptoms. So, also, as far as possible, tuberculosis in any of the other organs was eliminated. She grew steadily worse for a while, and at one time the dyspnea was so bad that it was thought tracheotomy would be necessary, but after a few months of local treatment (asepsis and lactic acid principally) the whole condition cleared up, the tubercle bacilli disappeared from the sputum, and the woman is to-day apparently perfectly well, and she has no signs of tuberculosis in any organ. Would not even the few cases—such as the above—which we all meet warrant us in giving a favorable prognosis in a certain percentage of these early cases of tubercular laryngitis?

As to climate, if in the homes we will enforce the same rules that are enforced in the Adirondacks and the other resorts, it seems to me we can get much the same results. I think probably most of us in the large cities have had patients under observation whom we could not send away, but who, by persisting in keeping in the open air and taking exercise, have often recovered. I have in mind at least two such cases which have practically recovered. As to the Adirondacks, while they are an admirable place of rustication for any of us, my experience with cases of tubercular laryngitis has been unfortunate in that locality, for only one case of the five or six which I have sent there has shown improvement.

As to operative interference, experience would seem to argue against curetting or otherwise roughly handling the inflamed larynges. The less said about the curette the better. I have never had any favorable results in my work from operative interference in any case.

Dr. W. S. Anderson, Detroit—There is only one point which I wish to make in regard to the treatment, and that is the use of intratracheal injections. While not a new method, I think it is not appreciated by the profession generally. The intratracheal injection of one or two drams will give relief in many cases when no other method will, and it does not interfere in any way with the use of other means. I use a syringe with a curved canula, which is introduced between the vocal cords. I use olive oil as a vehicle and dissolve in it 5 per cent. of camphor-menthol and 2 per cent. of guaiacol; 2 per cent. of iodoform may be used in olive oil. The relief in most instances is very marked, and it does not cause spasm or irritation except in a very few cases. If more generally used, I am sure the profession would get gratifying results from this method.

Dr. T. W. Corwin, Newark, N. J.—I have used, for about two years, tracheal injections of about the same character mentioned by the last speaker and in a great many cases they have given satisfactory results.

Dr. Charles H. Baker, Bay City, Mich.—Dr. Chappell referred to laryngeal cases being worse near large bodies of water. I would like to ask whether his observation is that laryngeal tuberculosis occurs more frequently in those sections than in other parts of the country. I practice near the Great Lakes, and I see few cases of laryngeal tuberculosis compared with general tuberculosis. As to local treatment, the Doctor did not mention one thing that I have found to give great relief. When tumefaction occurs before ulceration and when there is great distress, ichthyol in emulsion or oily solution or a watery solution—it makes little difference in what form it is applied—gives relief and seems to have an immediate ameliorating effect on the tubercular condition, causing often marked improvement without the use of any other local treatment. Of course, the usual constitutional treatment is given in addition.

Dr. Sargent F. Snow, Syracuse, N. Y.—In the treatment of these tuberculous conditions I have always found the lactic acid applications to be very satisfactory. But as my experience has gone on I find myself relying less and less on local treatment. In the past six or eight years it has been my fortune to have a number of cases that I have sent to the Adirondacks and Catskills. Sometimes the ulceration was so extensive that the voice was completely lost, and I could see no chance for good results, but if I sent such a patient to the mountains and kept him there winter and summer, the local problem was solved. I have had a case under observation for nine years in which there was an ulceration so extensive that it seemed impossible to have the voice restored. She is now teaching singing, in connection with her school work. This patient has been in the Adirondacks all the time, except, perhaps, two weeks at home in the summer. She has taught school continuously, and she has now two very good vocal cords.

It seems to me that the real question is as to whether there are tuberculous conditions in the other air passages; are they patients whose general condition is satisfactory? If the general tuberculosis is well in the second stage or further, we can do but little good. If they are in the primary or the early part of the second stage, a practically continuous residence in the Adirondacks solves the problem. Local treatment is to be commended for those who are compelled to remain at home.

Dr. B. A. Randall, Philadelphia—The question of early diagnosis is important. In otologic work one is loath to strip

and examine a patient, and yet the appearance of the ears and upper air passages often directs our attention to tuberculosis. The altered rhythm of respiration may make the case so plain that it will not be necessary to strip the patient. It seems to me that this is too important an indication to be ignored, for before there is moist crackling or other changes in the pulmonary sounds at the apices, this prolonging of the expiratory sound may be readily determined.

DR. WALTER F. CHAPPELL, New York City—I only advocate cocain in advanced cases, when orthoform and other remedies have failed. Orthoform is very good in some cases, but it fails at times. Dr. Baker asked about the frequency of tuberculosis of the larynx in the regions near large bodies of fresh water. I do not know that laryngeal tuberculosis is more frequent near large lakes, but the cases do badly there and at the seashore.

A CASE OF SARCOMA OF THE MAXILLARY SINUS, EXCISION OF THE UPPER JAW, WITH REMARKS.*

JOSEPH S. GIBB, M.D.
Professor of Laryngology and Rhinology, Philadelphia Polyclinic.
PHILADELPHIA.

In the preparation of a paper on malignant diseases of the nose and accessory sinuses read at the last annual meeting of the New York State Medical Association, occasion was given to search the literature of the subject. Among the many points of interest I was impressed with the unusual lack of literature on the subject of sarcoma of the accessory sinuses. So far as I was able to ascertain there are but four cases of sarcoma reported. Of these three cases were of the maxillary sinus and one of the frontal and ethmoid cells. This, of course, does not represent the frequency of sarcoma in this locality. We are all more or less familiar with these cases, either from personal experience or report.

It shows, however, a lack of appreciation of the importance of the subject, for our knowledge of rare and peculiar cases is increased by the publication of similar cases in which the individual methods of observation and treatment are outlined. With these thoughts in mind, and for the reason that the subject is of deep interest to me, I have considered the following case not unworthy of report:

NARRATION OF THE CASE.

F. O., male, aged 63, previous health good, family history unimportant. Early in October, 1901, he noticed a swelling below the left eye and suffered somewhat from irritation of the lids. For the relief of this condition he came to the eye department of the Episcopal Hospital. Soon after his first visit he became conscious of an irritating discharge from the left nostril and breathing from this side became obstructed. He was then referred to the nose and throat department where I saw him for the first time about October 15.

Examination.—There was tumefaction over the left cheek bone and puffiness of the left lower lid. An irritating discharge from the left naris excoriated the upper lip immediately below the entrance to the naris and he experienced much difficulty in breathing through this nostril. Examination revealed a mass occupying the left nasal cavity. This mass was reddish in color and rather soft; it bled upon the slightest touch. The growth filled the naris so that all the anatomic points were obscured.

Suspecting the nature of the growth a piece was snared off for microscopic examination. Free bleeding followed this slight operation. Suspicion pointed to the antrum as the source of the growth because of the accompanying swelling of the cheek and eye. Transillumination of the sinus gave distinct evidence of the presence of a body within the antrum.

Operation.—The nature of his case was pointed out to the patient and he was advised to have an excision of the upper jaw. He readily consented and was accordingly admitted to the hospital for this purpose. Some delay in the time of operation ensued because of the illness of the surgeon to whom the case belonged, so that a week or more elapsed. In this brief period the growth increased with amazing rapidity and the general symptoms became alarming. The growth absorbed the anterior wall of the antrum, appearing on the cheek, the skin over which became tense and red and palpitation elicited distinct fluctuation, and gave every evidence of the presence of a purulent collection. The growth also absorbed the hard palate and fluctuation was distinct in the roof of the mouth. He became septic and delirious, requiring restraint, and it was feared extension had taken place to the cerebral cavity. However, December 7, though his condition was not favorable for operation, he was prepared for the same and Dr. Hutchinson removed a portion of the superior maxilla and a large quantity of a semi-solid, sarcomatous-looking mass, pus and broken-down tissue from the antrum. The wound was thoroughly cleansed and every suspicious-looking mass curetted away. The wound was then packed with iodoform gauze.

Recurrence and Reoperation.—He reacted well from the operation, and by the 16th the wound seemed clean and healthy.

December 24 (17 days from the date of the operation) a small nodule was noticed on the posterior wall of the antrum. This continued to grow rapidly and by the middle of February filled the entire cavity and projected into the mouth. Ligation of the external carotid artery of the left side and complete excision of the superior maxilla, including the floor of the orbit and excision of all enlarged glands, were now advised. In consultation with Dr. Davis we agreed that this offered the most favorable chance for the patient and that should recurrence take place the carotid of the right side could be ligated. Accordingly on the first of March Dr. Davis first tied the external carotid artery and removed a few enlarged lymphatic glands in the neck. He then made a complete excision of the superior maxilla. The patient reacted well from the operation and has since continued to do well, showing no evidences of recurrence at the present time.*

The piece of growth snared from the nose was submitted to two competent pathologists and pronounced giant-celled sarcoma. Later a piece of growth in the antrum was examined by another pathologist who designated it a mixed round and spindle-cell sarcoma.

The interest in this case centers (1) in the location of the sarcoma, (2) the rapidity of its growth, (3) the means of diagnosis, and (4) the treatment.

LOCATION.

That the maxillary sinus is an unusual site for the development of malignant growths is attested by the few cases which have been reported. That it is not so infrequent as the statistics would lead us to believe I am convinced from my own experience and that of professional friends with whom I have discussed the subject. Several cases have come to my notice, though not directly under my control, where it seemed probable the starting point was the maxillary sinus. There can be no doubt in the case reported that the maxillary sinus was the original site.

THE RAPIDITY OF GROWTH.

Sarcoma of the nares is slow of progress as compared with other malignant diseases affecting this region. From a careful analysis of 111 cases it was found the average duration extended over a period two and a half to three years and that the growth was rather slow in extending.

There is very little data on which to base conclusions in the similar condition affecting primarily the maxil-

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

* The patient died in the early summer. He was suddenly seized with acute maniacal delirium and died before he could be removed to the hospital. No autopsy was obtained. It is probable the symptoms were due to an extension of the sarcomatous process to the meninges.

lary sinus. Levy's case extended over a period of three years. In Lamphear's case no mention is made of the duration of the growth and there was no recurrence in eight years after a radical operation. Such rapidity of growth as was seen in the case herein reported must be quite unusual. Observe that in six weeks from the time of the first manifestations of the disease the entire antrum and a large portion of the left nasal chamber is filled with the new growth. Degeneration and liquefaction of the growth had taken place and the osseous tissues were involved through pressure and absorption. Again, after the first operation, which was not a complete excision of the superior maxilla, recurrence was noticed in seventeen days, and in four weeks' time the entire cavity was filled and the growth projected into the mouth. Rapidity of growth is not entirely unique in sarcoma in this locality, for several cases are reported in Bosworth's statistics of nasal sarcoma in which the progress of the disease covers a period of a few months. It is, however, not the usual course.

THE MEANS OF DIAGNOSIS.

The presence of nasal discharge with a growth in the nasal chambers and concurrent swelling of the same side pointed to disease of the sinus and justified the removal of the nasal tumor for microscopic examination. Transillumination rendered invaluable aid in showing the antrum occupied by some foreign body. The natural inference was that this foreign body was of the same nature which the microscope showed the nasal growth to be, and the latter was a mere extension of the former.

METHODS OF TREATMENT.

The history of this case demonstrates, if further proof is necessary, the utter futility of any operation in malignant diseases of the nose and accessory cavities which does not include the entire removal of the growth. It were better not to interfere by surgical measures than do an incomplete operation. Nasal sarcoma is stimulated to increased activity by intranasal operations because such are necessarily incomplete—one can never be sure how much is involved out of the line of vision. Observe in the case reported the very rapid recurrence after an incomplete excision of the superior maxilla. It seemed at the time of this operation that all malignant tissue was removed, but in the light of subsequent events it would have been much better to have removed the entire upper jaw—which, at the same time, would have removed possibly infected osseous tissue and afforded increased amount of space for thorough inspection of the parts.

Ligation of the carotid, by starving the tissues, plays an important part in the treatment of sarcoma in the nose and accessory cavities. In the case reported it has doubtless contributed to the prevention of recurrence and it facilitated the operation by minimizing the hemorrhage. In this connection the work of Dr. Dawbarn of New York City should be mentioned. He advocates the ligation of both external carotids in the treatment of malignant growth in the nose and accessory cavities. As I have not had access to Dr. Dawbarn's article I am not familiar with his technic. In a conversation with him I gathered that his operation consisted in ligation and removal of both external carotids and their branches and that no attempt is made to remove the growth; the removal of the blood supply being thought sufficient to effect shriveling and render it inert.

It is, of course, too early to claim a cure in the case reported, but it seemed to me of sufficient importance to warrant the publication at this time.

1907 Chestnut Street.

DISCUSSION.

DR. PETER J. GIBBONS, Syracuse, N. Y.—Just now we might resort to the use of the *x*-ray in such a case, which is used, although at the present time it is more or less experimental.

DR. G. V. WOOLEN, Indianapolis—We have had an experience in Indianapolis to which it might be interesting to call attention. A case came to Dr. Sterne with an immense sarcoma affecting the axilla, neck and the groins. There was great asphyxia. At that time the Doctor was investigating the use of the *x*-rays, especially in connection with the treatment of malignant growths. He selected the upper growths in this case, the neck and axilla, for treatment and left the groins. He succeeded in breaking down the growths entirely, whereas those of the groins continued to increase. He lost his patient, he claims, through the liberation of large quantities of toxic material, which caused death from toxemia. His conclusion, in a premature way, as he stated when he brought it before our society, was that it would probably be undesirable to use the *x*-rays in internal work.

THE PROPHYLAXIS OF SINUS DISEASES.*

D. BRYSON DELAVAN, M.D.
PROFESSOR OF LARYNGOLOGY, NEW YORK POLYCLINIC, ETC.
NEW YORK CITY.

There can be no question that of late years diseases of the sinuses adjacent to the nose have been distressingly common. Case after case appeals to us for aid, all of the different sets of cavities show liability to involvement, and the processes of inflammation and suppuration are represented in a wide range of their typical manifestations. If the ultimate consequences of sinus disease were trivial and its natural course one which led to speedy recovery we might perhaps be pardoned for regarding it optimistically and for leaving its care to the healing forces of Nature. Unfortunately, however, there is no class of disorders which calls more urgently for relief, nor which if neglected creates more widespread and disastrous ruin. The extensive and irreparable destruction of important parts, suffering of unparalleled severity, long-continued invalidism and nervous depression—these and many other evils may easily result from the diseases in question.

In recalling these well-known facts it must be remembered that much brilliant work has been done for the cure of many of the most severe and difficult cases, and that patients who formerly dragged out existences of extreme and hopeless suffering, are to-day enabled to secure permanent relief. The operative treatment of chronic sinus disease is one of the chief triumphs of modern surgery, and as such is deserving of highest praise.

But while the cure of disease is an unspeakable benefit to mankind, its effective prevention is a far greater one. It is well, therefore, that we should give careful attention to the subject of this discussion, in the hope that through a better understanding of the causes of sinus disease some suggestions may arise through the aid of which a certain number of cases may be altogether eliminated, and others, destined by reason of neglect to fall into serious trouble, may be quickly rescued. The writer believes that a large amount of sinus disease could be done away with if the knowledge of the general physician were sufficient to recognize its predisposing causes, or, where it has already developed, to appreciate its early acute symptoms and to apply a few simple principles of cure.

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

All who have observed the course of acute sinus inflammation know that in many cases severe symptoms may be successfully met and a speedy cure effected by the prompt recognition of the trouble and its immediate effective treatment.

It may not be so generally understood that in many instances certain causes exist which directly predispose to sinus disease; causes in the presence of which exciting influences of comparatively little importance in a normal nose may assume dangerous proportions and become the occasion of serious results. It has seemed desirable, therefore, to present a few suggestions bearing on this subject.

In order to prevent these troubles it is necessary to know the various causes which may bring them about. These may be both predisposing and exciting.

PREDISPOSING CAUSES.

Anything which seriously hinders free drainage from the upper half of the nasal cavity may act as a predisposing cause of sinus disease. Malformations of this region are by no means always associated with diseases of the accessory sinuses, as we occasionally find the latter seriously affected in particularly well-formed and patent nasal cavities. On the other hand, malformations of the nasal cavities predispose to congestive troubles in general, and those in turn render the accessory sinuses more liable to accident. When acute inflammation of the sinuses has been actually established, there is no question that the above-mentioned conditions may contribute in an important degree to the severity and continuance of the attack; thus, an acute inflammation of the sinuses, which in a normal nose would have run a short course and terminated in spontaneous recovery, may easily become so aggravated by the lack of free drainage and by the increase of the inflammatory symptoms, due to pressure as well as to retained secretion, that the case may resist all efforts at cure, and in spite of the most skilful treatment become chronic. Where, in addition to deflection of the septum and deformity of the middle turbinates, the transverse diameter of the nasal cavities is especially narrow, invasion of the sinuses is particularly apt to be followed by serious results. Several abnormalities of the septum may be mentioned as contributing to the production of sinus disease. One of the most important of these is fracture of the septum with displacement, the narrowing occurring somewhere in the neighborhood of the middle turbinated body. Deflection of the septum without evidence of previous injury, by which one nasal passage becomes distinctly narrower than normal, may also be mentioned.

Catarrhal thickening of the tissues of the upper and middle part of the septum may be another cause, as may also be hypertrophy or unusual size of the so-called tubercle of the septum, that area of erectile tissue situated about the middle of the septum and opposite the middle turbinated body.

Again, the conformation and condition of the middle turbinated body itself are very important factors in the production of these diseases; thus, in case the middle turbinate is of abnormal shape, whether longer than usual in its perpendicular diameter or curved on itself, or again, where it is distended to the immense size sometimes found on the concave side of an extensively deflected septum, it will readily be seen that the normal drainage of the parts may be interfered with and obstruction easily created.

Congestive and hypertrophic conditions of the soft parts of the middle turbinates which interfere with drainage are another predisposing cause.

As to the general causes which may predispose to these diseases, it may be said that anything which promotes acute or chronic irritation of the nasal cavities or anything which tends to create catarrhal disorders would act as a predisposing cause of sinus inflammation.

EXCITING CAUSES.

The exciting causes of sinus disease are varied and cover a pretty wide field. Thus, inflammation of them may occur in several acute affections, among others: pneumonia, diphtheria, measles, scarlet fever, typhoid fever, smallpox and cerebrospinal meningitis. It is not an uncommon complication in croupous pneumonia. The frequency with which it has been observed during attacks of influenza is a matter now commonly known and recognized. The inflammation may extend directly to the sinus from the nose or nasopharynx or indirectly in the course of a general systemic infection. Sinus disease has also been attributed to an attack of facial erysipelas. It is questionable, however, whether erysipelas may not in many cases be due to pre-existing sinus disease, numerous instances of recurrent facial erysipelas having been observed in which the erysipelatous attacks have been done away with by the treatment and cure of necrosing ethmoiditis and similar diseased conditions of the accessory sinuses. Suppuration of the sinuses may also be associated with certain chronic diseases of the nose, such as specific ulceration, tuberculous disease and the various types of new growths, both benign and malignant. While nasal polyps may be a cause of the sinus disease through their influence in occluding the channels of exit of these cavities, it is generally conceded that they are far more apt to be the result of irritation due to a sinus discharge, and it is not likely that they can be eradicated until the latter has been cured.

It has long been known that certain cases of suppuration of the antrum of Highmore have been due to dental irritation. Inflammation may also be due to injury from fracture of the walls of the sinus. It has not infrequently been caused by operations on the nasal cavities in which the adjacent parts have been treated with violence, or instruments not properly aseptic have infected the parts. It has occurred from the removal of nasal polyps, through plugging the nasal cavities for epistaxis or for other reasons, and, in general, after any operations performed in the neighborhood of the middle turbinated body.

Attention has also been called to the fact that the extraction of teeth and division of the fifth cranial nerve have caused inflammation of the antrum. The peculiarly close relation between the channels of exit of the different sinuses renders infection of one from another a frequent accident, as has been well shown by Bryan and other authors.

Doubtless another prolific cause of irritation is the inhalation of dust blown up from the badly-cared-for streets of large cities and filled with countless possibilities of infection. It would seem, also, that the popular use of the racing automobile should contribute a large addition to the list of cases, as here the conditions contributing to their production are particularly numerous and favorable.

Again, in many cases of sinus disease the careful bacteriological study of the secretions has demonstrated the presence of various different micro-organisms; among these are the *Diplococcus pneumoniæ*, the *Pneumobacillus of Friedlander*, the *Bacterium coli communis*, and others. More commonly, however, varieties of the streptococcus and staphylococcus are found.

PROPHYLAXIS.

Of all the possible causes of these diseases, however, probably none is more common than local inflammation resulting from influenza. Just here the services of the physician may be invaluable. If he will recognize the importance of the severe coryza which accompanies this and allied disorders, do his utmost from the moment of its inception to prevent it, or at least to shorten its course, we can safely promise that the number of cases applying to the specialist for the relief of chronic sinus disease will be reduced to a small fraction of what is now the case. Care properly exercised towards the much despised "cold in the head" would save a vast amount of serious after-trouble.

A study of the predisposing causes of sinus disease at once suggests several important practical points; thus, any condition which occludes the natural outlets of the sinuses directly tends to the production of disease. It is very important, therefore, in fractures of the nose and in malformations of the septum and of the turbinates that this important consideration be kept in mind. The correction of a disfigurement and the opening of the nasal cavities for the free passage of air are not by any means the only considerations which should be entertained in the study of these cases. Even where external deformity may not be great and where the lower part of the nasal chambers is sufficiently unobstructed to admit of free respiration, the condition of the upper half of the cavity may be such as to demand earnest attention and perhaps careful operative treatment. This idea also applies to occlusion of the nasal cavities through swellings and hypertrophies of the soft tissues, many of which have a very direct influence in obstructing the sinus outlet. The practice recommended by some foreign authors of increasing the transverse diameter of a narrow nasal cavity by crushing the middle turbinated body against the outer wall of the nose is most unscientific, in that it directly favors occlusion of the sinus outlets.

ACTIVE TREATMENT.

There are probably few conditions in which more favorable results can be gained by prompt and efficient action early in the course of the disease than in acute sinus inflammation. The first symptoms of the invasion of the accessory cavities are not always easy to recognize. But while exceptional cases may often occur, as a rule the peculiar pain over the brow which accompanies frontal sinus involvement, the aching and neuralgia in the neighborhood of the cheek bone which attends the invasion of the antrum of Highmore, the peculiarly deep-seated, unusual sensations accompanying inflammation of the ethmoidal sinuses, are generally fairly evident. In any case, it is needless to say that violent inflammation of the nasal membranes themselves is likely to extend by contiguity to the linings of the adjacent sinuses, so that we may take for granted that in certain severe attacks of inflammatory intranasal disease the sinuses must almost of necessity be involved; or, if they have not yet become involved, that there is imminent danger of an extension of the difficulty to them. The pernicious practice of allowing a "cold in the head" to run its course is probably responsible for large numbers of chronic cases of sinus disease. In any case, however, an acute influenza—whatever may be its nature—should be watched as a matter of importance and should be treated from the very outset as a disease likely to produce grave results. Even if a given attack of acute influenza should not result in setting up long-continued sinus disease, the fact that one such inflammation predisposes the patient to others, which in turn, render him liable to sinus involvement, should urge us to use every possible measure for checking the more simple attacks.

The principles of treatment applicable in these cases are based on the most ordinary and well-understood rules of common sense and experience in the management of inflammatory conditions in general, and means are not lacking by which speedy and oftentimes brilliant results may be obtained. The administration of laxatives for the purpose of reducing the circulatory disturbance in the head, the internal exhibition of certain drugs, such as belladonna, for the purpose of contracting the blood vessels of the affected region, are both time-honored means for affording relief. Perhaps the most important recommendation of all is that the patient should be kept in an even temperature and that the surface of the body should be so stimulated as to favor the flow of blood in that direction; by this we mean that he should be put to bed and kept warm and comfortable during the height of the attack. Locally, the old-time methods have been supplemented by a number of new suggestions of extreme value. Here two principles of treatment are to be recognized; first, the fact that the disease is being kept up through the retention of irritating, if not absolutely poisonous, secretions, and, secondly, that on account of the swelling of the parts the natural avenues of escape are blocked and the already excessive amount of secretion is prevented perhaps absolutely from emptying itself. In this state of affairs success is attained by simply applying the grand axiomatic, surgical principle of free drainage and thorough cleansing of the parts. On this the treatment of these cases absolutely rests.

Just what remedies are the most reliable in the acute cases each careful observer must determine for himself. The writer has found much value in the following rules:

1. All local treatment applied in these cases must be absolutely unirritating.

2. The nasal cavities should first be carefully sprayed with a mild cleansing solution, following which the swollen tissues should be contracted by applications of a mild solution of cocain, not stronger than 4 per cent., and the approaches to the sinus outlets opened as widely as possible by the action of this drug.

The secretions should be removed as far as is possible from the regions before occluded by means of the cleansing spray; a spray of adrenalin should be applied for the purpose of increasing the power and adding to the duration of the effect of the cocain, and, finally, the parts should be protected by a light spray of liquid albolene. If these applications are made with sufficient gentleness and care the result will be immediate relief to the patient's distress with much ultimate benefit to the inflamed cells. Applied early in the history of the case, an attack which promised to be severe has been broken up by a single treatment. Several treatments, however, are generally necessary, many may be required, and sometimes it is only after a long course of patient effort that success is attained. Where the treatment must be continued the danger of the repeated use of cocain must be recognized and adrenalin substituted. Indeed, in many cases it is better to depend on the latter drug alone. During the height of the attack the recurrence of the nasal swelling may necessitate the repetition of the treatment several times a day.

The prevention of invasion of the sinuses in the acute infectious diseases already mentioned, is a matter not

always within the limits of our present knowledge. Thus, in diphtheria, measles and scarlet fever, attended as they are with violent local congestion of the nasal cavities, it is difficult to think of any safe means of treatment. In typhoid fever, smallpox and pneumonia, however, careful systematic cleansing of the nasal passages is most valuable for many reasons and is clearly indicated, not only for the prevention of otitis, but also for that of analogous inflammations of the accessory sinuses.

SUMMARY.

To briefly summarize the matter, in the prophylaxis of sinus disease much good may be accomplished:

1. By recognizing the conditions under which inflammation of the sinuses is likely to occur and, if possible, removing them.

2. Where removal of the predisposing conditions is not practicable, by guarding the patient against the various exciting causes which may determine an acute attack.

3. When acute inflammation is already threatened, by applying immediate treatment for its relief.

1 East Thirty-third Street.

ACUTE SINUSITIS.*

J. A. STUCKY, M.D.
LEXINGTON, KY.

On account of the irregularity in shape and uncertainty of size, location and communication of the accessory cavities of the nose, the diagnosis of the exact cavity or sinus involved in the acute stage of inflammation is frequently impossible. In the subacute or suppurative stage the diagnosis is not often difficult. Time will not be taken to refer in detail to these irregularities. The recent original research and publications made by Cryer of Philadelphia, B. Douglas of New York and Turner of London, have added greatly to our knowledge of the minute anatomy, and to them we are indebted for knowledge that enables us to deal radically and successfully with these pathologic conditions.

Attention is briefly called to the meati of the nasal cavities because the accessory sinuses communicate through them to the nasal chamber. These sinuses, or air chambers, both on anatomic and clinical grounds, are divided into two groups—anterior and posterior (Turner). The first group consists of the maxillary and frontal sinuses, and the anterior ethmoidal cells, all of which communicate with the middle meatus below the line of origin of the middle turbinate bone; the second, or posterior group, consisting of the posterior ethmoidal cells and sphenoidal sinus, open into the superior meatus, that is, above the level of the middle turbinate. These sinuses, or air chambers, are lined by a thin vascular mucoperiosteal layer covered by ciliated epithelium, studded with mucous glands, which is continuous through the ostium of each with the lining membrane of the nasal cavity.

The point made by B. Douglas regarding the sinuses of the small wings of the sphenoid should be especially borne in mind. He says: "These communicate, when they exist, on one side with the posterior ethmoid cell and on the other side with the recessus sphenoidalis. Above lies the brain, the optic nerve and the optic chiasm; below the nasal mucous membrane and the anterior part of the great sinus, and anteriorly the posterior ethmoid cell; externally, the optic nerve runs over the convex outer wall and when the sinus is large it may have here an important relation with the carotid artery and occasionally with the vidian nerve and wall of the orbit, so that an encysted empyema of this sinus may cause optic nerve paralysis, press on the carotid, paralyze the vidian or cause orbital pressure." A. Onodi has found in some cases there is direct communication between the maxillary sinus and the ethmoid or sphenoid cells, or both. The irregularities of the ethmoid and sphenoid are perhaps more marked than the others, but the irregularities are by no means limited to these, as all know who have operated on the frontal and maxillary sinuses.

ETIOLOGY.

As to the etiology of inflammation of the sinuses, obstruction of the natural outlet may be mentioned as the chief causative factor. Vascular dilatation associated with swelling or thickening of the mucous membrane, the formation of small masses of granulations, or even the presence of inspissated mucous may be the cause of the obstruction, and such closure leading to acute or chronic congestion, or even to inflammation and suppuration. Whether the retention of gases or the rarefaction of the air in the closed sinuses produces the congestion and pain as advocated by Vansant is yet an open question. Bacteriology throws little light on the source of the infection in sinusitis. The influenza bacillus is conceded by many to be the most prominent factor in the infection because of sinus inflammation being so frequently a sequel of la grippe. F. Furet has found not only the influenza bacillus, but also the pneumococcus, *Streptococcus albus,* and a large, long bacillus occurring in pairs and staining by Gram's method.

SYMPTOMS.

This trouble is usually ushered in with the general malaise attributed to grip, the severe "bone ache" being generally well marked. One of my patients has so accurately described the symptoms, and they harmonize so well with those of many others, that I give them almost verbatim: "Violent pain in brow and eyes, somewhat less in my cheek bones and back of head, all the front half of my head seemed alive with hot, throbbing pain. Every separate tooth was outlined with an individual ache. The muscles of my head and neck were stiff, the tissues over my eyes and forehead felt swollen and were tender to the touch. Light was painful and sharp noises were hard to endure, though I was partially deaf. I seemed to feel the noises in my body. One of the most distressing conditions was the stopping of all drainage in the nasal passages, and pain and discomfort were intensified by my efforts to clear these passages. The pain, sense of weight and fulness in my head was most acute in the morning. There was for some days the most intense and horrible tendency to mental depression (melancholia), that had to be continually fought against. An annoying and continuous nausea accompanied the pain in the head. The sense of taste and smell were so impaired that eating was a burden, though otherwise the appetite was good. Aside from the nausea there was really no distress outside of my head and neck. All these symptoms were intensified by any jarring of body, such as is caused by going down steps. Bending the head forward caused most acute suffering."

DIAGNOSIS.

The diagnosis of the exact sinus involved in the acute or inflamatory stage is impossible for reasons already

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Laryngology and Otology, and approved for publication by the Executive Committee: Drs. Emil Mayer, C. R. Holmes and G. H. Makuen.

stated. Anterior rhinoscopic examination shows the mucous membrane red, swollen and of glazed appearance—frequently little or no secretion is noticed unless it be found inspissated in the middle meatus. The turbinals, both inferior and middle, are swollen. Posteriorly the same condition of dryness exists with less swelling of the turbinals.

Transillumination in the average case is practically of no value unless there be suppuration; then its diagnostic value is by no means reliable. Notwithstanding the violent pain in the head and the general discomfort of the patient, the pulse is usually slow and the temperature little above normal—frequently the morning temperature being from one-half to one and a half degrees subnormal. The skin is dry and parched. The symptoms simulate those of mild cerebral compression, and the severity of the subjective symptoms is out of all proportion to the temperature and pulse.

TREATMENT.

The indications for treatment are entirely antiphlogistic, the chief indications being, first, to relieve suffering and discomfort; second, to prevent suppuration.

The patient is to be put to bed, room to be kept quiet and all bright light excluded as long as eyes are sensitive. Arouse the secretions with full dose of calomel (5 to 10 grs.) combined with small quantity of ipecac, this to be followed in six or eight hours by saline cathartic—sodium salicylate and sodium bromid, 10 gr. of each, pilocarpin gr. 1/10 to 1/20 in four ounces of water every two or four hours till pain is relieved and free diaphoresis established. The activity of the skin is to be maintained by frequent bathing, great care being used not to chill the patient when giving the bath. Dry heat applied to frontal and occipital regions by use of hot-water bags. Locally, the nasal douche, used both anteriorly and posteriorly, of hot normal saline solution, or Seiler's solution in one-half strength, twice daily; this not only keeps the passages clean, but is very soothing and grateful to the sufferer.

If the nasal passages are occluded or uncomfortably "stuffy" a small quantity of the following sprayed into the nostrils every two or four hours is most effective and rapid in its action: Sodium chlorid 5 gr., resorcin 5 gr., adrenalin sol. (1 to 1000) 1 dr., aqua 7 dr.

This strength of adrenalin is all that is necessary, practically no reaction following its use. Cocain and opiates are mentioned only to be condemned, because of their unpleasant reaction and having a tendency to thwart the objects aimed at in the treatment. Only in exceptional cases have I found their use advantageous.

Special care should be given the systemic conditions, the secretory and excretory functions maintained in an active state. On account of the great susceptibility to recurrent attacks, convalescence should be guarded and the patient kept indoors until thoroughly restored.

Simple sinusitis, whether involving the ethmoid, frontal, maxillary or sphenoid, usually subsides spontaneously under appropriate antiphlogistic treatment. When suppuration occurs the imprisoned pus must be evacuated and thorough drainage maintained or serious results may follow.

Removal of the anterior end of the middle turbinate when it is so swollen as to occlude the natural outlet of the sinus is indicated in either inflamatory or suppuration trouble. In many cases this is the only surgical treatment needed.

DISCUSSION.

ON PAPERS BY DRS. DELAVAN AND STUCKY.

DR. C. M. COBB, Lynn, Mass.—There are certain diseases that we are not likely to escape some time in our life. Almost everyone has one or more of the acute infectious diseases. A very large proportion of the cases afflicted with the acute infectious diseases have some sinus disease. Then we have this complication that requires vigorous treatment, and not the treatment with douches, especially in the sinus complication that follows an actue infectious disease—that is, if you expect to escape trouble with the ears. The insufflation of calomel has done much good in my cases following the acute infectious diseases. There are sources of infection of the sinuses that we can escape, as in the cases due to dirt that you get into the nose either with water or by facing dust in the streets or halls, etc., which is intensely infectious. The pain in acute sinus disease is not a reliable indication as to which sinus is involved. As I will attempt to show to-morrow, in those cases I have transilluminated, the pain was not a sure indication as to which sinus was involved. One word in regard to the rarefication of the air in the sinus. It is claimed that after the closure of the natural opening the air is absorbed. We must remember that the composition of the air is practically 22 parts oxygen and 78 parts nitrogen. The oxygen is readily absorbed, but the nitrogen remains unabsorbed for months, especially in cavities, as in the pleural cavity or the sinuses. So practically 25 per cent. of the air may be absorbed, but that does not suffice to enable the cavity to soon be entirely filled with serum.

DR. EMIL MAYER, New York—In the first instance, to be purely technical, we should avoid the word sinusitis, as it is not correct. Secondly, regarding the treatment of these afflictions. We are accustomed to read that the antrum of Highmore is washed out through the natural openings. It is time that this statement be shown to be incorrect. By means of this section of a skull which Dr. Cryer kindly permits me to use, you will see that in order to enter the antrum of Highmore in a normal nose a probe must be bent like a shepherd's crook, and hence, if we do enter the cavity and inject fluid, it would have to flow up hill in order to be cleansed. In a small number of cases, if the opening is abnormally situated, cleansing in this manner is possible, otherwise not.

DR. D. A. KUYK, Richmond, Va.—Concerning the treatment of the mucous lining of the nasal passages and the adjoining sinuses, we should resort more than is now customary to internal therapeutics. In an experience of twelve years as a general practitioner before adopting my specialty, I met a great many acute inflammations of the nasal passages and the sinuses, especially the frontal sinuses. Now, if we administer pilocarpin, we do undoubtedly get an intense serous exudation, but at the expense of the tissues by reason of the increased arterial blood supply or active congestion, due to the vasomotor paralysis produced by the drug, causing swelling of the tissues rather than a shrinkage. The use of the calomel purge is of the greatest benefit.

If we want to produce diaphoresis, let us do so by giving a combination of liquor ammonia acetatis, spirits of niter and acetate of potash. From this we get thorough relaxation and diaphoresis without any prostration. After, say, six hours we can begin to give small doses of atropin sulphate, say, 1/500 grain every 15 minutes for six or eight doses, then once every 2 hours.

Atropin seems to have a selective action on the mucous lining of the nasal chambers and the accessory sinus. Under this treatment the supra-orbital and infra-orbital and nasal pressure pain quickly subside, the serous discharge diminishes, the head feels clear, and the prolonged acute inflammation of the nostrils and sinuses is averted.

DR. B. A. RANDALL, Philadelphia—I agree with what has been said in reference to the value of atropin in treatment. I have suffered frequently with a sharp inflammation of the antrum of Highmore, with an outpouring of a straw-colored fluid, and in such cases I have found myself promptly and greatly relieved by the employment of atropin. I always employ it in the acute cases. As to Dr. Stucky's paper, I would

like to speak warmly in favor of transillumination in a very considerable number of cases. It is not infallible. Instead of being a method given us by our European brethren, however, it was demonstrated fully by a Philadelphia man years before the publication of it by Heryng. Dr. Addinell Hewson demonstrated it in 1885 in the general assembly room of the Pennsylvania State Medical Society. It seems to me the transillumination method is one of considerable value and I have very keen recollection of one case of sarcoma of the antrum of Highmore, in which the transillumination showed some clouding months before the opening of the antrum when probing, even then failed to demonstrate the presence of a sarcoma as later demonstrated. If we use the method in complete darkness with an electric light pushed to the verge of destruction, as is needful to secure sufficient intensity of illumination, and seek to illumine the pupils, we will often find it of very great value in diagnosis, for it often gives positive or negative information that may be relied on.

I have been struck by some statements as to the inaccessibility of the sphenoid by the probe in the ordinary examination. I have passed my probe into the sphenoid sinus in more than half the cases in which I have attempted to do so, and in some cases of extreme trouble this is of very great importance. In a case in which I was called to a child apparently near death from meningitis, I examined the eye-ground, the ear and the nose. In the nose I found one chamber free and the other with a little pus in it, which I removed. Then I passed my probe into the free sphenoid and found nothing there. In the other sphenoid I found pus, and I passed my little alligator forceps into the sphenoid, opened them and withdrew them with rotary traction, thus breaking away the front wall and giving free drainage. I got a demonstration of the presence of pus in the sphenoid in that case and permitted it to drain away, although too late to prevent the fatal result of the meningitis.

DR. GEORGE F. KEIPER, Lafayette, Ind.—I have tried to relieve the pain in various ways and have succeeded sometimes by the use of quinin. I believe in giving quinin and calomel together until the patient has taken three or four grains of calomel and the bowels have moved thoroughly. For the application of heat I know nothing better than a little Japanese pocket heating stove. It is better than the hot water bottle, because the hot water bottle needs to be more or less continuously changed to keep it at an even temperature. The Japanese heating stove may be wrapped, and in this way you secure more even heat continuously. But no one remedy will suffice in all cases, for every patient is a law unto himself. Many remedies may have to be tried before we secure a desirable result.

DR. SARGENT F. SNOW, Syracuse, N. Y.—In this subject of sinus trouble, that has been so well elucidated, I think we have a field that gives nose and throat men an opportunity to do the most beneficial work, work that will bring them the most credit, or about as much as any we can do. This is true not only in acute but also in chronic cases. In 1889 I prepared a paper on cephalagra and tic douloureux, which was presented before the American Rhinological and Otological Society. In that paper I cited cases, showing the source of tic douloureux to be frequently in the accessory sinuses, not always a pustular collection, but often caused by pressure by polypoid masses accumulating in the cavities. I have had a series of these cases since that paper was written that has impressed me more and more with the importance of that factor in causing those painful neuralgias. We have also the most severe forms of headache coming from these sinus accumulations. In my personal observation I have seen two cases so extreme that when the patient had the seizures there would occur a condition of spasm, with loss of consciousness. They were cured by clearing out the sinuses. I had one case of tic douloureux that resisted everything until I drained the sphenoidal sinus. This patient was under observation for two years without effecting a cure until I obtained relief for her in that way. In cases showing asthmatic symptoms, we can almost always determine a sinus trouble. I feel great confidence in undertaking those cases, because if we drain the sinuses properly we are almost sure to get definite results, although not always absolute cures. I want to take issue with Dr. Mayer in reference to one statement he makes, as to the possibility of syringing the antrum and cleaning it out. While I do not advocate this as a cure for chronic cases, still I have found it effective in subacute and acute cases. I have now two chronic cases with pus in the antral cavity that will not submit to operation, where I syringe out the antrum whenever the accumulation becomes too great. I agree with Dr. Mayer that it is impossible to syringe out some cases, but I do know I often find cases in which I can reach and syringe the antrum thoroughly.

DR. H. M. CRYER, Philadelphia—This is a subject which is very interesting to me, because I have often said that a probe or sound can not be passed through the nose into the antrum through the ostium maxillare of a normal subject. I have sections here from which slides were made and the pictures were shown on the screen at our meeting held at Columbus in 1899. This section is an anterior-posterior one, made by cutting down through the center of the orbit, the maxillary sinus and the molar teeth. We find two outlets to the antrum passing into the nasal chamber. The anterior one is the normal ostium maxillare. The posterior one is abnormal, sometimes called an accessory opening. These abnormal openings are often caused by the enlargement of the bulla ethmoidalis, which, in many cases, as it was in the specimen here shown, causes the closure of the hiatus semilunaris posterior to the normal outlet of the maxillary sinus, thus preventing the fluids from the maxillary sinus, the frontal sinus and the anterior ethmoidal cells from passing into the middle meatus of the nose; they all become engorged and the fluids will eventually pass in the direction of the least resistance. If the alveolar process had been thin, as it is in some cases, the fluid might have passed through it into the mouth, but in this case it is strong, and as the abnormal opening is posterior to the bulla ethmoidalis, the fluids pass into the posterior part of the middle meatus. Dr. Snow would have no trouble in syringing the antrum of this character, because the nozzle of the syringe could be passed through the abnormal opening. I have found the abnormal or accessory opening as large as the tip of my little finger, and those are the cases in which our friends wash out the antrum through a tube introduced through the nose. In the normal skull, as can be shown by perhaps twenty specimens here on the table, it would be impossible to pass a sound through the nose into the maxillary sinus.

DR. NORVAL H. PIERCE, Chicago—It is possible, I believe, in a certain number of cases to wash out the maxillary antrum through a natural opening—that is, without piercing the walls of the antrum. As has been said, the gentlemen who believe that they can syringe out the antrum through a pre-existing opening have struck cases in which there are no accessory openings. I would not be one who would impress you with some extraordinary skill, some wonderful tactile sense, but I have washed out the antrum through the natural openings. These openings have, in all probability, been accessory openings. But that does not make a difference in point of fact. There is very strong reason for believing that in diseased antra these accessory openings are larger and more numerous than in healthy skulls. Hartman, Zuckerkandl and a great many other men believe that this is true, that it is a part of a rarefying osteitis in which these accessory openings occur. Therefore, I believe we are justified in all cases of antral disease, whether they be acute or chronic, in first seeking for the natural opening into the maxillary antrum in the middle meatus before resorting to an external operation.

DR. ROBERT C. MYLES, New York City—Nearly all the literature is confined to the chronic cases. There is no doubt that what Dr. Delavan has said is true, that the condition of the nose is often the cause of the sinusitis. If that is true, we should remove the cause if possible. By overheating the houses, as we do in our modern civilization, we cause and intensify the conditions of acute sinusitis. We have also the progressive dentist as a cause of many cases, by filling the teeth that formerly were extracted. In my experience a hot

room with steam, the patient being kept in the dark and quiet, has aided the case in progressing favorably. In regard to the value of transillumination, the amount of evidence it conveys to one depends largely on how he may use it. One should take into consideration the darkness of the room and the intensity of the light. There should be a standard lamp. It is not infallible, but it helps us often to find out what is there. I do not believe that it is pus that causes much of the opacity, but that it is the thickened blood-filled tissues.

DR. G. MCAULIFFE, New York—Two points have appealed to me in acute sinusitis, and they are the persistent application of cold instead of heat and also the benefit derived from a good nose bleed. Nature induces a depletion later by the exudation of serum and pus. In regard to the choice between heat and cold, we know that cold is infinitely better where the bacterial potentiality outweighs the tissue degeneration. Where the tissue degeneration outweighs the invasion of bacteria, heat is better. I find the application of the ice bag diminishes the risk of further implication. I believe the advantages from anterior turbinectomy result not so much from the enlargement of the middle meatus as from the depletion of the hypermia in the middle meatus.

DR. GEORGE L. RICHARDS, Fall River, Mass.—I have had some experience in acute sinusitis, and I would like to endorse Dr. Stucky's remarks as to the value of syringing with warm saline solution in these cases. It certainly gives very great relief and washes out much of the mucus. In reference to the treatment of acute empyema of the frontal sinus, difficult as it is to pass a probe or canula up into it, I have several times relieved a patient who came to my office suffering greatly, by the passage of a probe up into the sinus. The relief was not due to the cocain which preceded the use of the probe, for there was no relief until the probe was passed into the frontal sinus.

DR. EDWARD PYNCHON, Chicago—Considerable has been said about the use of fluids in the washing out of the sinuses, and nothing has been said about the use of air, which will clean the nasal passages as well as water. The railroad companies use compressed air to clean the upholstering in the coaches, and I have put the same principle in practice in the treatment of the nose. With the hand nebulizer, when provided with a suitable tip, I think I have succeeded in driving medicated nebulæ into the sinuses just as well as I could a fluid. For acute sinusitis, the use of politzerization, with the external ears closed, so the air is forced to enter the sinuses, will often relieve the headache and sense of fulness. Of course intranasal deformities are most often responsible for sinus disease, and we might say that conditions of the nose that impair the ventilation of the attic are the causes thereof. When there is no impairment of the drainage and ventilation of the attic, there will be no sinus disease. One attack of sinus disease undoubtedly predisposes to a recurrence thereof. We should correct, as far as possible, the deformities of the nose which are instrumental in impairing the drainage and ventilation of the attic.

DR. L. C. CLINE, Indianapolis—I would like to endorse what the Doctor has said. I believe you can reach these cavities by nebulizing and stop the growth of these microbic agencies. Still, I do not believe we can wash out the cavities well with solutions. We can do something to stop the inflammation. I was struck especially, during the reading of the papers, by the fact that gentlemen will come to the meeting of this Association once a year from the Atlantic to the Pacific and from the Gulf to the Lakes and read papers on the prevention of disease, but did you ever hear of lawyers coming together and discussing how to prevent lawsuits? When a man gets hurt on the train or street car, some lawyer is immediately after him to try to induce him to bring suit. On the other hand, we are here to try to prevent disease.

DR. ALLEN DEVILBISS, Toledo, Ohio—In a case of acute sinusitis I would no more think of trying to wash it out than I would to wash out the gonococci in a case of urethritis. If you want to carry the infection back and produce a case of posterior urethritis, use a syringe. So it is in the cases of acute sinusitis; you will carry the germs farther on by trying to wash them out. If you have pent-up secretion, secure complete drainage and, as a rule, it will take care of itself.

DR. PETER J. GIBBONS, Syracuse, N. Y.—The principal cause of acute synovitis is a congested mucous membrane, whether it is from hay fever or any other disease. I wish to call special attention to the fact that the principal cause is exactly the opposite to what we get relief from. If you use suprarenal extract you get a contraction of the vasomotor system. The principal cause mentioned here is influenza. To talk of influenza and the various colds as being local diseases I believe is wrong. Influenza is a constitutional disease; it is no more a local disease than is syphilis a local disease in chancre. Influenza is caused by electrolytic dissociation of inorganic salts in the body into ions. Take sodium chlorid in the body, and any electrolytic dissociation that may affect it will give sodium positive and chlorin negative. Its effect is local on the mucous membrane or on the dilatation of the vasomotor system of that part. Chlorin mixes with hydrogen in the ethmoid sinuses without combining until the patient is exposed to light. The actinic rays cause them to unite and form hydrochloric acid. The ethmoid cells have something to do with chlorin, iodin, hydrogen and other ions and hydrochloric acid. We will find the causes of hay fever, hives, and kindred diseases in the ethmoid sinuses. They are the safety valves of the human body. The germ of influenza, then, is the same as the trout in the spring brook; the trout comes to the spring brook, not the brook to the trout. I believe inside of five years the medical profession will make a marked advance in the study of the physiologic function of the sinuses. There is a physiologic function of the various sinuses. And do not forget the tonsil. The tonsil eliminates the substances that the sinuses throw down. For the next few years keep track of the functions of the sinuses, and you will find it will be the greatest subject before the medical profession. I think Dr. Cryer agrees with me, the more the sense of smell is developed the larger the sinuses are, and the smaller the sinuses the less the sense of smell.

DR. J. A. STUCKY, Lexington, Ky.—In regard to what Dr. Mayer says, I thought over the term sinusitis a good deal before using it, but I did not know what other term to use. I am sorry Dr. Mayer did not name it. I said nothing, you will notice, about washing out the sinuses. In the last clause I said that if suppuration results it becomes a surgical case and as such it must be handled. Dr. Randall I think misunderstood me. I have always used transillumination, but I believe it is unreliable. I am glad Dr. Myles called our attention to some matters in this connection that I neglected to mention.

THE *X*-RAY IN CANCER AND SKIN DISEASES.*

CHAS. W. ALLEN, M.D.

Professor of Dermatology, New York Post-Graduate Medical School; Consulting Dermatologist to the Randall's Island Hospitals; Consulting Genito-Urinary Surgeon to the City Hospital, Etc.

NEW YORK CITY.

Of all the recent advances in the treatment of skin diseases, none has attracted more widespread interest than that of phototherapy. The treatment by light, while not strictly a novelty, has received such an impetus since Finsen first brought out his treatment of smallpox by red light, that actinotherapy, as well as the more recent radiotherapy, can almost be considered a method introducing a new era in the therapy of many affections. While the reports from the application of the Finsen method abroad appear most encouraging, comparatively little of a positive nature is to be reported from this side of the Atlantic. Radiotherapy, on the other hand, although of much more recent development,

* Read at the Fifty-third Annual Meeting of the American Medical Association, in the Section on Materia Medica, Pharmacy and Therapeutics, and approved for publication by the Executive Committee: Drs. A. W. Baer, A. B. Lyons and W. J. Robinson.

has advanced with such rapid strides that already sufficient reports are available to justify certain definite conclusions. I can not attempt here to collect statistics from the scattered literature, but must content myself with a brief report of my personal experience during the past year.

At the present time I can make a report on 35 cases of cancer of various kinds in which radiotherapy has been employed. Of these 9 were carcinoma of the breast, 6 recurrent and 3 primary. Of these one has died, 3 have ceased treatment, 2 of their own volition and one by my advice, and 5 are still under treatment and all showing improvement. One cancer of the chest wall, with extensive involvement of the skin, extending on both sides of the line of incision, has been discharged apparently or symptomatically cured. The opposite breast is, however, suspected of being involved, and treatment may be resumed for this reason. Of the other, internal or deep-seated cancers, there has been one death in a recurrent cancer of the neck following operation for cancer of tongue; one case of cancer of the rectum, which had improved decidedly up to a certain point, has been forced for some time to interrupt treatment; a cancer of the pelvic organs following removal of the uterus is still under treatment. Three cases of sarcoma, or more properly speaking, 2 of supposed sarcoma, one of the jaw and one of the chest, and a small round celled sarcoma of the finger now involving the meninges of the cord and probably other internal organs, are still under treatment, no positive report of progress being warrantable. In the small cell sarcoma the very worst prognosis has been made and the rays are administered for the patient's mental comfort rather than from any expectation of lasting benefit.

Beside these cases, there are now under treatment 6 patients, one with a rodent ulcer of the lower third of the left arm of twenty years' duration, involving nearly the entire circumference, being nearly three and one-half inches in length and penetrating to the bones and tendons; an epithelioma of the lip in a woman; a recurrent cancer of the lip in a man, and a multiple epithelioma of the face, forehead and neck. This last patient has had the disease for about twenty years, and has lost his left eye by operation on account of the disease, which several years ago invaded the periorbital structures.

Fifteen cases in all have been discharged as cured. These include 6 lesions involving chiefly the nose and lip, 2 the nose and eyelid, one the cheek and eyelid, one the region of the cheek just beneath the eye, 2 the chin, one the forehead, one the chest wall, one the face and eyelid and one of the cheek. Of the cases remaining under treatment, 2 can be regarded as nearly well, and a third has apparently recovered, so far as the skin lesions are concerned, while the eyes, which are both affected by the cancerous process, are making decided progress, though the sight of one eye has been, in all probability, permanently destroyed.

This case is worthy of a moment's consideration, the subject being a boy of 15 years of age, afflicted with the rare dermatological condition of xeroderma pigmentosum, which first began to show itself three years ago. It is of interest to note that this affection, which probably depends in a measure on the effect of exposure to sunlight for its development, should be beneficially influenced by light in another form.

Of the skin diseases proper subjected to the Roentgen ray there have been seven cases of lupus erythematosus, all of which have shown decided improvement, but only one of which is considered cured. There have been four cases of lupus vulgaris; three can be regarded as cured and one is still under treatment very much improved. Eczema of various kinds is represented by ten cases, in which the ray appeared to assist, at times, other coincidentally employed methods. Five cases of inveterate psoriasis have been subjected to the rays with pronounced benefit in at least one of them. Eight cases of sycosis of inveterate form have all shown decided improvement, four having been symptomatically cured. In hypertrophic and rosaceous acne, 2 at least out of 5 cases have shown a marked effect beyond what could be expected from treatment coincidentally employed. Beside these there have been one case of leprosy, the patient claiming that improvement has taken place, and 3 cases of favus, in one of which at least the ray has appeared to be of decided benefit.

Taking, then, this series of cases as a basis for a personal estimate of the value of the *x*-ray as a therapeutic agent, my belief is that while it shows nothing especially brilliant, there are sufficient positive factors to enable us to state that in a class of obstinate and, in many instances practically incurable maladies, so far as other known methods are concerned, we possess in the *x*-ray an adjunct to treatment which bids fair to prove of incalculable benefit.

Care must be exercised in its employment, for it is an element of power which may be exerted for evil as well as for good. Severe cancer, I believe, must be treated with careful oversight, and not left to electricians and non-medical workers in *x*-ray laboratories, with occasional observation on the part of the physician. Symptoms may arise with great suddenness which require modification or entire withdrawal of the rays for a season with substitution of careful medical treatment.

30 East Thirty-third Street.

DISCUSSION.

Dr. C. E. Skinner, New Haven, Conn.—The paper deals with a field of therapy that is entirely new and with diseases that hitherto have been beyond help, such as cancer and other forms of malignant growth, which it had been found by ordinary means impossible to keep in check, and which, in spite of all efforts hitherto, have gone on in their course of destruction. The first question that is usually asked about a new treatment is about the permanency of the results. I would not regard the question of permanence as of so much importance as the actual fact of improvement itself. For instance, if we can succeed in stopping the course of a cancer so that it is cured for the time, it is a great gain, even if in the course of six months or a year the treatment has to be repeated. Even temporary improvement is a great advance, and patients would be willing to return at intervals for treatment that will arrest the disease, even if it does not definitely cure it. I have personally treated, during the last eight months, forty-five cases, most of which have been helped. Seven or eight were breast cases, all of them primary, and none broken down. In only two did I succeed in materially reducing the size of the lumps in the breast; all the others improved so slightly that I can not speak positively, except on one point: in all of the cases, the progress of the disease was checked.

Now, as regards the effect of the rays on metastasis, my opinion is that the metastasis would have occurred more frequently had the *x*-rays not been used. I believe that we are going to find a use for surgery, in the future, in connection with the *x*-rays, to an extent which can not now be anticipated. For instance, in a case of cancer of the breast, with involvement of the axillary glands, and some evidence of extension to the bronchial structures, I think that it would be the proper thing to remove the great mass of the disease by surgical operation, and then apply the *x*-rays until all evidence of the

disease disappears. I have seen several cases of lupus which did not improve, but I have also seen cases get much better.

With regard to the possible unfavorable influence of the *x*-rays, I have seen several cases give evidence of autointoxication while under treatment. One in particular, which had been doing very well, suddenly developed uremia and died in three or four days. It had given no signs of it before. The question, from the standpoint of scientific interest, of whether or not a toxin is developed or liberated and absorbed into the circulation during the treatment by *x*-rays is one of importance and deserving of consideration, especially in those cases where the growth is deeply seated. From a practical standpoint, however, I do not consider that it matters much, as almost any patient afflicted with inoperable cancer will accept nearly all risks from autoinfection or anything else, if, by so doing, he may secure a chance to get rid of the malignant process.

DR. A. W. BAER, Chicago—Dr. Allen spoke of metastasis possibly being excited by the rays. I hardly think there is much in that theory. The rays have been used for some length of time and perhaps a little stronger than necessary, but I have not seen anything that would warrant this opinion. Some patients take less kindly to the treatment than others, but I have never seen it cause metastasis. When cancer forms in the breast opposite from that which has been treated by the *x*-rays, it is because the germs were there also, before the treatment had been instituted. As regards autointoxication and death from uremia, it is possible that the *x*-rays had caused an increased discharge of toxic material into the circulation, which might set up uremic poisoning. In the case cited by the preceding speaker, I think the case would have died in a short time, anyhow. We can hardly blame the treatment for the unfavorable result. The question of sarcoma is a very interesting one. I was very much surprised to learn that any surgeon would recommend operation in osteosarcoma. I have yet to see a sarcoma of the bone which did not return in a very short time after operation. I think the surgeon referred to had carcinoma and sarcoma somewhat mixed. Surgeons do not, as a rule, care to operate on sarcoma of the bone. They will be very glad to be rid of this class of cases and turn them over to the *x*-ray operator. From what we have learned of the *x*-ray, I feel warranted in saying that where there is an inoperable case of carcinoma, or of sarcoma, after the surgeon has removed what he can of the diseased tissue, and has done all that he can, the patient should then be subjected to the *x*-rays. In a case which I supposed to be one of tuberculous ulcer I applied this treatment with striking result. I only made six applications, each lasting 15 or 20 minutes; the first application dried up the secretions and it commenced to heal rapidly, and a few more applications entirely healed it. In this case I used a mask and held the patient's face within 2 or 3 inches of the tube. The proper duration and distance depend on the patient and the kind of apparatus used: whether a static machine or a coil, as well as on the character of the tube. I have never yet seen a static machine that heated the platinum, but I have seen a coil apparatus heat the platinum in a quarter of a minute. Experience with each form is required in order to overcome difficulties and to obtain the most satisfactory results.

DR. HENRY VARNEY, Detroit—I have worked with both the static and coil. I have found—as has just been stated—that the coil will heat the platinum point very rapidly, because of its high amperage, compared with the static. On this account, one can not make a very long exposure with the coil, even with the mildest ray. That variety of machine is expensive to operate and dangerous to the patient. I do the greater part of my work with a static machine, and find it most satisfactory.

With a highly interrupted small static exciter, exposures may be given every day, bringing about a gradual stimulation which is less liable to destroy new tissue. I do not say that it will not cause a burn, because in the treatment of sarcoma and carcinoma, I have found it necessary to burn into the true skin before the condition was influenced, but with it the extent of the burn can be gauged from an erythema days before a dermatitis or destruction of the true skin occurs. With regard to cases of uremia or, more likely, ray-toxemia, from overloading of the eliminative system; as would be caused from an extensive burn, a great amount of interest is excited. Within the past month patients have complained of rheumatism weeks after exposures have been given, where large areas were exposed, and it was the first time they had had an attack. I think there is need of further investigation in this direction, and I suggest that Drs. Allen and Skinner and other operators study the excretions of patients before, during and after treatment, and see if more light can not be thrown on this condition resembling rheumatism.

Referring to the penetrating power of the static apparatus as compared with the coil, I believe that with a hard tube great penetration may be had. Six months ago it was thought that we could get any penetration or stimulation. I had a case of epithelioma that involved the whole breast, axilla and two inches on the back, measuring seven and three-quarter inches in length by eight and three-quarters in width. In exposing the ulcer anteriorly, the back healed almost as rapidly as the anterior surface, by the rays passing through the patient's body, showing clearly the penetrating power of the static apparatus. I have many cases of osteosarcoma and carcinoma that have been operated on, the rays being given to prevent a recurrence. My experience warrants the statement that every case of malignant nature that has been operated on should subsequently be treated with the rays, in order to prevent recurrence, because of the influence of the rays in restoring normal cell action.

DR. CHARLES W. ALLEN, New York—I am very glad to hear the remarks concerning sarcoma and surgical operation. This is a tender point with me, because a reputable surgeon must know that most sarcomata ordinarily do not do well after surgical operation, and the interest of the profession is now excited by the favorable reports of the effects of the *x*-rays on this class of cases. In view of these reports, I think such patients should have the benefit of this treatment.

As regards the occurrence of toxic symptoms, I have observed joint and muscular pains of rheumatic character during treatment. This suggested to my mind the possibility of a poison being given off into the general system from the growth, and being thrown off so suddenly that the eliminating organs had not been able to take care of it. The source is the mass of broken down organic elements resulting from destruction of the growth. This is what I meant by saying that the *x*-rays are capable of doing harm, and that their application should not be left in the hands of inexperienced and non-medical men. Dr. Varney has said that you will have a warning before a serious burn occurs, by the appearance of an erythema. A burning sensation is at times the earliest warning. When the erythema appears the warning is usually too late, because burning has already taken place.

As to the kind of machine to employ, my preference is for the static for therapeutic effects. It has been claimed by some that the whole effect of radiation is due to electric action on the tissues. This may possibly be true; we can not say positively yet to what the action is due. When the rays pass through the body, some of the effects may be due to electricity. Different methods may be combined with the *x*-ray treatment, internal remedies may be given at the same time and caustic pastes may be at times employed to hasten the process. A preliminary course of treatment before cutting might be of advantage, as well as the post-operative. I am treating a tumor in the breast of a young woman, and holding the question of operation in reserve while watching the effect on the growth. It would be of advantage, it would seem, to have the progress of the disease checked previous to operation. After all operations, however, I would use the *x*-rays for a considerable time, perhaps a number of months subsequently, in order to prevent the return of the disease. I have had no experience as to the value of *x*-rays in the treatment of cancer of the stomach, or, at least, none that will warrant any deductions as to the value of this treatment, though I have treated cancer of intestinal, rectal and pelvic organ origin with evidence of decided effect.

RADIOTHERAPEUTIC OBSERVATIONS.*

JOSEPH ZEISLER, M.D.
PROFESSOR OF DERMATOLOGY, NORTHWESTERN UNIVERSITY.
CHICAGO.

The employment of the mysterious *x*-rays for the treatment of various skin diseases has ceased to be the monopoly of a few privileged promoters and is gradually becoming almost indispensable in the work of the up-to-date dermatologist. Much has been learned in this new field of practical medicine. More remains to be accomplished before the new agent can be handled with scientific accuracy. At the present moment there is still a deplorable diversity of opinion concerning some vital points in the theory and practice of radiotherapy. The controversy as to the real active principle emanating from the Crookes' tube is apparently still unsettled. Freund and Kienboeck may be mentioned as important representatives of the two opposing factions. The former, after persistently attributing the bulk of the *x*-ray effects to peculiar electric discharges or waves from the tube, seems of late to somewhat recede from his position. Kienboeck, who regards the Roentgen rays as the efficient element, has a host of followers, among whom I am willing to be counted. It seems to me that comparisons with the well-known effects of the Finsen light therapy, and even with those of continued exposure to ordinary strong sunlight, make it more than plausible that the clinical manifestations following *x*-ray exposure can be explained without giving to the electric shocks coming from the tube more than a coincidental rôle. With all deference to certain experts in electricity I can therefore take little stock in their attempts to establish those clinical results on the basis of electrolytic action.

TECHNIC.

The whole question here alluded to has more than merely theoretic value. Inseparably coupled with it is the selection of the proper tube for our work, whether a hard or a soft one. Whoever is after the display of electric action will take a hard tube. He can get an abundance of electric waves out of it with a scarcity of rays. Accordingly, the desired irritative or resolvent effects on the skin will be slow in making their appearance. On the other hand, the soft tube emits hardly a spark when in contact with our hand, but gives a light rich in Roentgen rays. Its clinical effects are prompt and energetic. These are established facts and admit of no discussion. Furthermore, it is generally admitted that the rays of a hard tube have a penetrating action and may easily cause far-reaching destruction, while the rays of the soft tube are absorbed by the upper layers of the skin.

Much of the success in *x*-ray work depends on the proper apparatus. The static machines are hardly fit for dermatologic purposes. A good induction coil only is to be considered. In my own equipment, which has given perfect satisfaction, the direct street current is utilized, allowing a maximum of 150 volts. It is conducted into a wall plate containing volt meter and ampere meter, rheostat and speed regulator, allowing up to 2,400 interruptions to the minute. From the wall plate the current is directed through a motor and into a rotary mercury-petroleum interruptor, and from there to the coil, which is capable of a 12-inch spark. The latter is so constructed that of the three parallel spirals constituting the primary spool, one only, two or all three may be energized through a special system of switches. In this way all gradations from the softest, barely noticeable light to a rich green one can be generated. Without resorting to the rheostat the voltage varies accordingly from about 65 to 85, while the amperage recorded shows in inverse proportion from 4 to 1½. I purposely mention these figures as very different from other authors; for instance, Schiff and Freund, who advocate a current of 12 volts with an amperage of 1½ to 2. The fact of the matter is that while proper registrations of the intensity of the current are of interest, reference to them is of value only when the identical apparatus is used by another. The essential element in determining the energy with which we work is the character of the light irrespective of either voltage or amperage. There are some special photometric devices designed to ascertain the strength of the light, but they are little used and of minor value for practical work. To the beginner the frequent use of the fluoroscope will be of inestimable service, and Kienboeck's directions in this regard, and his sketches illustrating the shadow of the hand from tubes of varying degrees of vacuity were much appreciated by me. Gradually one learns to judge the condition of the tube by mere inspection and by the aid of the ear. The intensity of the light is, however, only one of the factors constituting the desired dosage. The distance of the tube from the radiated surface and the time of exposure are of equal if not more importance. The often-heard advice to use only the "softest light" must therefore be taken *cum grano salis*. If I place my tube with its strongest possible light at a proper distance, say 40 centimeters, I can use it safely for what might be called a mild exposure.

As to the tube itself, I would strongly recommend the use of self-regulating tubes after the pattern of the Müller tube. While much more expensive than the ordinary cheaper ones they have a great endurance and I have repeatedly used them for more than one hundred strong exposures without exhausting them. Two principal methods of employing the rays may be mentioned. The one first advocated by Schiff and Freund, and followed by Pusey, is to use a soft light in short sittings in frequent, even daily, intervals until a reaction sets in. This is surely a safe method though rather slow in many cases, and as for out-of-town patients, who come for an occasional treatment only, quite impracticable. The other plan, according to Kienboeck, is to give what he calls a normal exposure, i. e., the use of a powerful light for a period of about twenty minutes in a single sitting, after which an interval is allowed and the reaction is waited for. One such normal exposure will often be sufficient to produce the dehiscence of hair from the radiated area. This method requires a good deal of experience. I have followed it repeatedly and have never had any serious consequences. I have more often, however, taken the middle ground and have used ten-minute exposures at intervals of a day or two to the number of from five to eight, when usually a decided reaction would take place. The proper method to be followed will depend to a large measure on the nature of the case and other circumstances, as I may mention later on. Whoever is making extensive use of the Roentgen rays is bound to have, sooner or later, some unpleasant experience with the much-dreaded *x*-ray burns. This is due to the well-known observation that the effect of the radiations is cumulative and that the reaction, even after powerful exposures, requires eight to ten days to become at all noticeable and will then

* Read before the American Dermatological Association, at Boston, Sept. 19, 1902.

gradually reach its climax within the following week or two. Unfamiliarity with this important fact may lead the beginner to persist in continued strong exposures up to a point when damage can not be undone. The three or four cases in which I produced a powerful reaction, consisting in acute dermatitis with oozing, crusting, etc., yielded readily to simple treatment within a week and caused little anxiety to either patients or myself, and left no permanent injury. I have never caused any sort of ulceration or sloughing. This may be explained from the fact that the light from the soft tube, which I have employed exclusively, has a rather superficial effect and does not penetrate into deeper tissues. Yet I feel that in the future even temporary dermatitis will easily be avoided by me, and my remarks may serve to keep others from similar accidents, for the ideal way of using *x*-rays in the majority of cases is surely to produce our results with the least irritation. In this connection a word about individual idiosyncrasy may not be amiss. Kienboeck believes that there is no such thing. Still the time required to produce a reaction surely varies in different patients, and particularly is there a notable difference in the resistance in various tissues. Pathologic cell aggregations, for instance lupus nodules, will be influenced much more readily than normal skin.

The protection of such parts as are not to be exposed to the rays is an important point in the technic. I have used for this purpose thick sheet lead, which is easily molded and cut into any desired shape, and had them lined with flannel. I would particularly warn against the careless exposure of the lips, which are most susceptible to irritation by the rays. In treating the face I always cover the eyes and the hair of the head.

During the six months, from March 1 to September 1, I have subjected 81 patients to radiographic treatment as follows: Lupus vulgaris, 1; lupus erythematosus, 1; scrofuloderma (tuberculosis of the shoulder joint), 1; hypertrichosis, 11; sycosis, 4; acne (all forms), 34; epithelioma, 9; psoriasis, 3; lichen planus hypertrophicus, 2; dermatitis staphylogenes, 1; eczema, 4; keratosis palmaris, 3; clavus, 1; pruritus, 1; hyperidrosis nasi, 2; non-dermatologic affections, 3.

I shall in the following very briefly and summarily report my observations in these cases:

LUPUS VULGARIS.

To the many cases of successful treatment of this affection by *x*-rays recorded in literature I am able to add one more, a typical instance of this disease.

Case 1.—My patient, about 50 years old, has been affected by lupus of the face since his early childhood, and has ever since been under treatment of a more or less radical character. I have myself had him under my care for the past eight years with little more than temporary benefit, having employed the well-recognized former modes of treatment, as cauterizations, curetting, dissection of the nodules, galvano-cautery and the like. The affection consisted in multiple, dry, deep-seated gelatinous nodules, isolated or forming small patches and practically covering the whole of the right cheek, extending over the bridge of the nose and encircling the lower eyelid, which as a result of surgical interference, undertaken in early childhood and consisting in an unsuccessful transplantation of skin has ever since been entirely everted. From the beginning of March to the end of July I made use of *x*-ray exposures in this case, starting at first on a small patch the size of a dollar. Seven ten-minute sittings during a period of about ten days caused a distinct superficial irritation, which developed promptly into a shallow eroded surface showing small depressions in the place of the former nodules. With nosophen dressings the patch healed up within about a week, giving a smooth, slightly reddened scar. In this manner the principal locations of the trouble were gone over successively. During the latter part of the treatment the whole area, as far as possible, was subjected *in toto* to mild ray exposures, and the interesting observation could be made that an irritation would appear only where lupus tissue was still present, while the previously treated areas exhibited no sign of further irritation.

While I am not prepared to pass final judgment about the outcome in this case, I am able to say that the result of the treatment so far was in every way highly satisfactory and far superior to any other method known to me, except, perhaps, that of Finsen. The perfect painlessness of the treatment and the smoothness of the scars are particularly noteworthy.

LUPUS ERYTHEMATOSUS.

A patient who is still under my care had a very characteristic and inveterate case of this affection.

Case 2.—A women, 56 years old, who had a lupus covering almost the whole of the face, with isolated patches behind the ears, was treated by me with *x*-rays during the two months, July and August. Three treatments a week for ten minutes with a strong light, at a distance of about 15 cm., were given to one side of the face only, while the other was treated with resorcin lotion. After four weeks the improvement on the radiated side was very marked, the color of the patches becoming very pale, and the desquamation being markedly diminished. A period of rest was allowed for this side, while the other half of the face was then likewise exposed with similarly good results.

SCROFULODERMA.

Case 3.—A young man, 23 years old, came to me April 15 with two large ulcers on the left upper arm, showing all the familiar characteristics of scrofuloderma. They distinctly connected with a tuberculous focus in or about the shoulder joint, and copious masses of thin, yellowish pus were discharged with each dressing from those ulcers. The patient was emaciated and had temperatures from 101 to 102. Radiations were given 3 to 4 times a week with a powerful light, at a distance of about 10 cm., over the whole region of the shoulder and including the ulcerated surfaces. After only six exposures the discharge of pus became very scanty, and disappeared almost entirely within the next three weeks. At the end of five weeks' treatment the ulcers were healed up, with the exception of a small area the size of about a pea, when the patient desired to be temporarily dismissed in order to go to his distant home. I have quite recently seen him again, and found him in every way much improved; the pain in the shoulder joint almost entirely gone, the mobility much improved, the weight of the patient increased by twenty-three pounds, absolutely no temperature, and the former ulcerations entirely healed up. There was, however, a small new abscess formation on the posterior part of the shoulder, on account of which the radiations were resumed.

HYPERTRICHOSIS.

I have often heard the remark from colleagues engaged in this line of work that they consider the treatment of hypertrichosis by Roentgen rays as a very delicate and uncertain affair. One of them, in answer to my direct question, once mentioned that he had given over seventy exposures to a woman thus afflicted. My own experience in the eleven cases thus treated have made me rather optimistic concerning what can be accomplished here. I have invariably made use of what has been before referred to as normal exposures, and have found that three to five such exposures, given at intervals of a week or two, will produce complete epilation. As several of my patients were living out of town and could come for a treatment only at long intervals, this method was the only one to be selected. The reaction consisted, as a rule, in marked pigmentation and temporary erythema which yielded gradually.

My patients have all been instructed that the epilation following one series of treatments is not to be considered as permanent, but that radiations should be resumed at intervals of, at first, two months, and later on longer periods without waiting for a return of the hair.

Whoever has had much experience in the electrolytic destruction of superfluous hairs will be bound to consider this new method a veritable boon to both operator and patient. One lady, with a very extensive growth all over the chin and somewhat on the cheeks, and who had formerly received many electrolytic sittings at my hands, remarked to me, after her third *x*-ray treatment, when all the hair from the radiated surface had fallen out, that she would never under any circumstances again submit to the electric needle.

As regards the final effect on the skin, I have been unable in my cases to verify Ehrmann's observation of an atrophy of the skin following this treatment.

SYCOSIS.

Of the four cases of sycosis which I have treated, two were very severe and inveterate. In one case it had affected the whole chin for a period of two years; in the other the lip had been the seat of the trouble for more than four years. The cases were both of the coccogenic variety and showed multiple follicular miliary abscesses. The treatment required was seven exposures for the one and eight for the other. The exposures were given at a close distance for ten minutes daily. The result of the treatment surpassed my most sanguine expectations. After two or three radiations pustules ceased to form. The reaction produced was very moderate. Defluvium commenced about two weeks after the beginning of the treatment and with it all inflammatory phenomena disappeared completely. The skin looked entirely normal, except slightly pigmented and reddened. These cases have since remained under my continued observation. About two months after epilation had become complete new hair began to show and has since grown out all over the affected areas. In spite of this there is so far no sign of relapse. Absolutely no other treatment had been given in these cases.

ACNE.

The thirty-four cases mentioned above comprise several varieties and all degrees of severity of acne. Five of them were instances of acne rosacea; one belonged to the type of acne necrotisans; four cases were indurated and pustular acne of the back and shoulders. The bulk of them were, of course, of the ordinary type of acne of the face, many of them of the very severest and most rebellious nature. It would entirely surpass the intention of this communication to go into details of all these cases. I would only remark in general that their management differed considerably from that employed in the previously named affections, in that the exposures were rather mild in character, the distance of the tube, according to its light, being from 20 to 40 cm.

My plan in these cases is usually to start in with three treatments a week for from two to three weeks. After this exposures are given twice weekly only for a time, and later on about once a week. A beneficial action can usually be noticed during the second week, when few new pustules are noted and the comedones seem to shrink and dry up. The accompanying seborrhea oleosa of the face is very promptly influenced. Some of the severest cases which I have ever treated were cured in from four to six weeks and have so far remained well.

If I think of the many years of hard and persistent work which I have formerly given these cases in the way of local treatment, consisting in the opening of abscesses, the removal of comedones, curetting, caustic applications and the like, with but fair results, and compare with that my present management of these cases and its almost uniformly excellent therapeutic effects, I can only regret that Roentgen's wonderful discovery was not made twenty-five years ago.

I am not prepared to draw final conclusions from my observations as to the etiologic nature of acne, but my long-held belief, that constitutional causes are foremost in its production, has now become considerably modified.

EPITHELIOMA.

From all appearances the use of *x*-rays for the eradication of epithelioma means a remarkable progress in this department of surgery. My own observations in nine cases of this kind are certainly such as to make me rather enthusiastic in this respect. My cases were all of the superficial variety. As to location, three were situated on the side of the nose, one on the lower lip, one on the lower eyelid, one near the tip of the tongue, one on the glans penis, one on the back of the hand and one on the forehead. Three of them were relapsing forms and had been previously treated by me by curetting and cauterization. In these latter cases the diagnosis had been established previously by microscopic examination. In the others this additional help to the diagnosis was considered undesirable, as a removal of tissue would be contrary to the conservative plan of radiotherapy. The treatments were given with a strong light, the distance of the tube being from 5 to 10 cm.; the sittings being ten minutes, repeated at daily intervals for a time, and then only every two to three days. The case of epithelioma of the lower lip was demonstrated before my class at the Northwestern University before the beginning of the treatment, and afterwards when cured. It required ten treatments during a period of four weeks. The one on the tongue yielded to twelve exposures given during three weeks. In only one case was there produced a reaction amounting to severe dermatitis. In most of them the exposures were interrupted at the first sign of a slight irritation and further results waited for. In all of them, I am happy to record, at least for the time being, a recovery.

A comparison of this method with all others known, both by surgical means and by caustics, must necessarily establish a vast superiority of radiotherapy, not only as regards its absolute painlessness, but also as regards the condition of the scars. Whether the results attained in my own cases and in the many reported by Pusey and others will prove permanent, remains to be seen; but to my mind the elective and deep-reaching action of the rays seems more radical than any surgical interference possibly could be.

PSORIASIS.

The three cases of this affection were selected with regard to special location of the disease. They were cases in which a few regions only were invaded by particularly stubborn manifestations; in one of them the knees only, in another the arm, showed a large infiltrated scaly patch; in a third the lower limbs were exposed to the rays. Exposures were made with a mild light at a distance of from 15 to 20 cm., in order to take in the whole affected area. Results were noticeable after from eight to ten exposures, and were on the whole satisfactory. In one of them the benefit has lasted for more than four months. We know from other observations recorded in literature that beneficial results by *x*-rays in

psoriasis are, however, not to be considered as permanent.

LICHEN PLANUS.

Similar results were obtained in two cases of lichen planus hypertrophicus located over the tibial region. One such patch, which had obstinately resisted various plans of treatment, even as energetic as thorough curetting, disappeared in an almost marvelous way after four strong exposures, given at intervals of five days each, and left the skin in a perfectly normal condition.

ECZEMA AND PRURITUS.

I have made use of *x*-rays only for isolated, chronic infiltrated patches of eczema, and my results seem to me very encouraging. One case of pruritus genitalis was much benefited by three mild exposures.

KERATOSIS PALMARIS.

I am sure that most dermatologists will agree with me concerning the great difficulty of successfully treating this condition. My own experience, at least, has always been very disappointing. The three cases of this affection which I submitted to radiotherapy were inveterate forms and covered in one instance the palmar surface of both hands, including the fingers, and in the other two circumscribed patches of the size of a dollar on each palm. The effect of the rays in these cases was, to say the least, surprising. One case seemed perfectly restored after five strong exposures.

CLAVUS.

CASE 4.—About the middle of July I was visited by a young gentleman, 23 years old, who complained that for the past two years his life had been made perfectly miserable by the presence of numerous soft corns on the soles of his feet. The affection was symmetrical and consisted in upward of sixty soft corns distributed over the plantar surfaces of all the toes and the adjacent regions of the sole. While a single corn may be a trivial affection, a trouble like this one surely deserves the earnest attention of the dermatologist. I learned from my patient that all sorts of treatments, including excision, keratolytic ointments, special pads, etc., had been tried in vain, and I therefore resorted at once, as an experiment, to the use of *x*-ray exposures. I gave twelve daily exposures with a strong light, at a distance of 10 cm., for ten minutes each. No visible reaction resulted, but the treatments had to be discontinued as I left for my vacation. Three weeks later, when I returned, my patient exhibited his feet to me, and to my great delight he was absolutely and perfectly free from all his corns and has remained so to this day.

HYPERIDROSIS NASI.

Two cases of this kind were subjected to radiotherapy, with the expectation that the rays would assist in limiting the excessive oiliness in analogy to their action in acne. Ten mild radiations were given in one of these cases at intervals of from three to four days, and the result as regards the size of the follicles and the secretion was satisfactory.

DERMATITIS STAPHYLOGENES.

CASE 5.—This was a remarkable case of an inflammatory affection, covering the back of the right hand, consisting of an eruption of multiple pustules, weeping and the other signs of an acute dermatitis. This condition seemed to me to be secondary to previous energetic treatment by the home physician, Dr. Sauerhering, Wausau, Wis., consisting in electrocautery for a trouble, the nature of which I could only guess, but in regard to which I had microscopic findings by Professor Zeit of Northwestern University, who declared that there was nothing malignant present, at any rate no tuberculosis. As the condition had rebelliously resisted continued treatment in various ways before, I decided to employ *x*-ray exposures. These were given with a strong light at a distance of about 10 cm. for ten successive days, when there was a decided erythema surrounding the affected patch. The pustules, however, had ceased making their appearance after the first few treatments, and the oozing had become considerably lessened. The patient was very anxious to leave for his home, but reported to me two weeks later that his hand was perfectly cured.

Of non-dermatologic affections I have used the rays in two cases of acute epididymitis, but was unable to say whether they helped the progress of the cases very much. In a case of hip-joint disease, in which I was asked to administer the rays, the effect in alleviating pain was very noticeable.

CONCLUSION.

Were I to attempt an explanation of the beneficial action of the *x*-rays in all these cases I would surely side with those who deny any particular effect on microorganisms, but who, basing their opinion on microscopic evidence, as does Scholtz, attribute to the rays a special affinity for pathologic cell formations, which, under the influence of the rays, undergo metabolic changes and even entire disintegration.

In conclusion, I can only say that my experience with radiotherapy so far has made me an ardent advocate of it, and I believe that until it is replaced by something still more marvelous it will constitute one of the most effective weapons in our fight against a large class of dermatologic affections.

THE PROGNOSTIC VALUE OF TUBERCLE BACILLI IN SPUTUM.

LAWRASON BROWN, M.D.
RESIDENT PHYSICIAN, ADIRONDACK COTTAGE SANITARIUM.
SARANAC LAKE, N. Y.

The sputum of each patient at the Adirondack Cottage Sanitarium is carefully examined every six weeks. In this paper the results of these observations carried out at the sanitarium during the last two years have been made use of to determine the possible prognostic value of quantitative and qualitative changes in the tubercle bacilli occurring in the sputum of phthisis. Before giving the results of the observations it might be well to recall briefly a few facts which, though thoroughly familiar, are of sufficient importance to review at this time.

Pulmonary tuberculosis has no characteristic form of sputum. It may vary in quantity from almost nothing to even 1,000 c.c. in twenty-four hours. The absence of sputum is no better sign of the absence of pulmonary tuberculosis than is the absence of cough. An abundant, mucoid, more or less frothy sputum, which often contains no tubercle bacilli, at times marks the onset of miliary tuberculosis on a chronic or less acute form of the disease. In fibroid tuberculosis of the lungs there may be little or no expectoration and no tubercle bacilli may be found for long periods.

The character of the sputum macroscopically is no absolute criterion of the presence or absence of the tubercle bacilli. Tubercle bacilli may occur in watery mucoid sputum, as well as in the usual mucopurulent variety. Tubercle bacilli may occur by millions in one part of a specimen and be absent from another. The bearing of this fact on the number of the bacilli in a specimen is readily seen.

The staining properties of the tubercle bacillus depend on its resistance to decolorization. As some hold that many of the tubercle bacilli in a preparation are not stained when it is ready for examination, the great value of sufficiently overstaining is easily seen. Carbol fuch-

sin is the best stain. If the quick method of employing heat is used a small flame is best. The fluid should be brought just to boiling, or better, until bubbles are seen to collect about the thicker parts of the smear. This heat should be kept up one to five minutes, or until crystals of fuchsin form on the surface of the fluid. The preparation should never be allowed to become dry on account of the difficulty in decolorizing. If the "cold method" is employed, the preparation should be left completely immersed in the carbol fuchsin for twenty-four hours.

Nitric acid (25 per cent.) and alcohol are the only safe agents to be used in decolorization, which can, if necessary, be controlled by the low power of the microscope. In the routine examinations after admission to the sanitarium Gabbett's method is used.

Recently some German observers have called attention to a number of bacilli which resist decolorization by acids and more or less resemble the tubercle bacilli in appearance. These have been described under the names of timothy-hay bacillus, grass bacillus, the butter bacillus, etc. Like the smegma bacillus and the bacilli of syphilis and leprosy, they all stain in carbol fuchsin and resist decolorization by acids to some extent. Ophüls of San Francisco and others in the last few weeks have published a list of several cases of pulmonary gangrene in which the sputum contained an acid-resisting bacillus.

With Gabbett's solution (1 gm. methylene blue in 100 c.c. 25 per cent. H2 SO4) some of these bacilli may escape decolorization and consequently nitric acid and alcohol should be used in any specimen for diagnosis.

"The tubercle bacilli," writes Fischel,[1] "is not an end form, but one form of the cycle of a rod-shaped bacterium." It usually occurs as a rod-shaped organism 1.5-3.5 microns long and about 0.2 microns in breadth. It has been seen 11 microns long. The shorter the bacillus the more apt it is to be straight. It is usually bent, sometimes curved, crescentic, or even like a spirillum or spirochete. It occurs at times in chains, and branching forms have been recorded by a number of observers.

The beaded forms have caused much discussion. Koch, in his early papers, held the clear refracting spaces to be spores, and many have followed his lead. They occur 1 to 8 in a bacillus, and are separated in stained specimens by round- or rod-shaped granules deeply stained in a lightly-stained capsule. The clear spaces are now held to be vacuoles, due to plasmolysis. Every observer has noted "nucleated" tubercle bacilli, i. e., bacilli containing more deeply stained rounded masses. These resist decolorization more strongly than the remainder of the bacillus, and at times resemble short chains of cocci. This is the explanation of the affirmation made by some that tubercle bacilli may become cocci. That these, too, are not spores is upheld by the fact that they have not been shown to resist drying and disinfection to any greater degree than the bacillus, nor have they ever been shown to germinate.

The club- or knob-shaped swellings at the end of the tubercle bacillus in some specimens are asserted by Coppen Jones[2] and others to be spores. This observer would place the tubercle bacillus very near the actinomyces, which reproduces itself in this manner. But it is much more likely that this form, with the two preceding, are all types of degeneration.

The arrangement of the tubercle bacilli in any specimen can not be told from what is found in a single slide. They occur often in clumps, often diffusely scattered throughout the specimens. At times they occur in groups of two, three or four, with their long axes more or less parallel. Occasionally they are found to be intracellular, in leucocytes or alveolar cells. Very occasionally they occur in enormous masses, such as are found in smears from cultures.

In tabulating I have used Dr. Trudeau's classification, which is substantially as follows:

Incipient stage: Slight local, with little or no constitutional involvement.

Advanced stage: The localized disease—process extensive or in an advanced stage; or slight local pulmonic invasion, with rather marked constitutional involvement or with complications.

Far advanced stage: Marked signs of pulmonic disintegration, with marked constitutional symptoms.

Improved condition: Physical signs showing process less active, or general health improved with symptoms relieved or abated.

Arrested: No activity in process in lungs, with absence of fever and other constitutional symptoms.

Apparently cured: Abnormal physical signs absent, or if present only slight and indicative of healed lesion. Absence for some months of pyrexia and of sputum or of sputum containing tubercle bacilli.

In tabulating the number of tubercle bacilli I have, with a few modifications, used Gaffky's scheme,[3] which is extensively employed at the foreign sanatoria.

1. Only 1-4 bacilli in whole preparation.
2. Only 1 bacillus on average in many fields.
3. Only 1 bacillus on average in each field.
4. 2-3 bacilli on average in each field.
5. 4-6 bacilli on average in each field.
6. 7-12 bacilli on average in each field.
7. Fairly numerous on average in each field.
8. Numerous on average in many fields.
9. Very numerous on average in many fields.
10. Enormous masses on average in many fields.

The modifications I have adopted consist in replacing "fairly numerous" by "13-25"; "numerous" by "about 50"; "very numerous" by "about 100 or more." In using this table Gaffky recommends that a Zeiss homogeneous oil immersion 1-12 and a No. 2 ocular at a definite tube length be employed.

TABLE 1.—Statistics of various stages treated with the frequency with which tubercle bacilli were discovered in the sputum.

Condition on Admission.	T. B. Found.		Condition on Discharge.				
			Apparently Cured.	Discharge Arrested.	Improved.	Unimprov'd.	Failed.

Total		259	71	115	61	3	9
Per cent.			27	44	24	1	4

Of the 169 cases with tubercle bacilli 71, or 42 per cent., had lost their bacilli on discharge. Of these 71 cases 52, or 73 per cent., were advanced, 7, or 10 per cent., far advanced, and 12, or 17 per cent., incipient. Of these incipient cases 9, or 75 per cent., were apparently

cured; of the advanced 10, or 19 per cent., were apparently cured. From these figures may be seen:

1. That the earlier the diagnosis the better were the chances for recovery.

2. That when the diagnosis was made before tubercle bacilli were found in the suptum, i. e., before ulceration had begun, the chances for recovery were at least twice as good and, on the whole, seemed many times better.

3. That when tubercle bacilli were once found, while a goodly number were arrested (many of which will no doubt be "cures" later), only a comparative few were "cured" during their treatment in the sanitarium, which on an average was four or five months.

These observations seem to draw us inevitably to the conclusion that we must leave no stone unturned to make in pulmonary tuberculosis an early diagnosis and to subject the patient to treatment immediately.

TABLE 2.—The frequency of the occurrence of tubercle bacilli in the sputum.

			Apparently cured Per cent.	Arrested. Per cent.	Improved. Per cent.	Failed. Per cent.

In 150 cases careful observations were made on the number, appearance and distribution of the tubercle bacilli in the sputum. Of the 150 cases 13, or 9 per cent., were apparently cured; 85, or 57 per cent., arrested; 41, or 27 per cent., improved, and 11, or 7 per cent., failed.

The number of tubercle bacilli seemed to vary on the whole directly with the severity of the case. Thus, the number "Gaffky" was IV in the cases apparently cured, VI in the arrested, VII in the improved and VIII in the cases that failed. The number "Gaffky" of any case was not based on one or two preparations from one specimen of sputum, but on two preparations from a number of specimens of sputum. During the past year we have discharged four patients, each of whom had tubercle bacilli in his sputum in enormous and innumerable numbers on one or more examinations. One of these was discharged apparently cured, two arrested and one improved. The masses of tubercle bacilli probably came from a disease process of a similar nature in each, i. e., the sloughing of a necrotic mass. Three of the cases had large cavities, one was an incipient case, showing a very slight lesion. In the latter the bacilli disappeared, while in the other cases, though they diminished somewhat, they were at times present in considerable numbers. My observations lead me to hold that as a patient improves there is frequently a steady decrease in the number of tubercle bacilli. The continuous occurrence of large numbers of tubercle bacilli indicates, as Brieger[4] says, the probable existence of a cavity. The occurrence of many and very few tubercle bacilli at intervals suggests a cavity that is occasionally blocked.

The absence of tubercle bacilli in the sputum is the condition *sine qua non* of healed tuberculosis, for, as Dettweiler[5] says, of what value would be the long-held maxim that the tubercle bacillus is the cause of tuberculosis, and where the tubercle bacillus is there is tuberculosis; of what value, otherwise, he says, would this be? The continued presence of bacilli in the sputum does not necessarily mean that the disease is in active progress. Dr. Fowler[6] reported a case in 1895 where bacilli had been found on every examination for fourteen years. During that period the patient was actively at work, and was, at the time of the report, better than he was in 1882. Dr. Trudeau has had a somewhat similar experience, tubercle bacilli being found for ten years, the greater part of which the patient spent in active work.

When we recall that only a fraction of the number of bacilli in any preparation appear stained when it is examined; that old foci may give off very few and young foci no bacilli at all, however actively they are forming; that the occlusion of a bronchus may shut off the focus entirely for a time; when we consider these things we see how little can be inferred from the number of bacilli present in any single preparation.

As regards the appearance of the bacilli, my notes would indicate that "beading" occurred equally in all classes of cases. The length seemed to vary somewhat with results of treatment. There were fewest long and short bacilli and most medium-sized in the cases apparently cured. The number of long and short bacilli was greater in the arrested and improved cases and most in the cases that failed, but the difference was not marked. The variation in thickness was not pronounced sufficiently to enable any conclusion to be drawn from it, and may be explained by differences in staining. The cases that failed contained the largest number of irregular bacilli as well as the largest number of the deeply-staining bodies previously mentioned.

The distribution of the bacilli has been carefully noted by many observers. The occurrence in clumps and the parallel arrangement of many, or even two bacilli, is said to evidence a favorable state of development and lively growth. Groups of short bacilli are held by some to betoken a bad prognosis.

The clumping of beaded forms, Brieger[4] believes, shows destruction of lung tissue. Clumping occurred in 69 per cent. of the cases apparently cured, in 78 per cent. of those arrested, in 80 per cent. of those improved and in 82 per cent. of the cases that failed, showing that there is a slightly greater tendency to clumping in the less favorable cases. It is difficult to say much in regard to the individual clumps, and from

my notes it would seem that clumps composed of bacilli lying close one to another form about the same percentage of clumps in all cases. Clumps of loosely distributed bacilli occurred more frequently in the cases that failed. Bacilli occurred diffusely scattered in practically all specimens.

Chains of three or more bacilli and pairs of bacilli with their long axes parallel gave no data for prognosis.

It is interesting to compare these results with some obtained in the laboratory. Theobald Smith[7] describes the bovine tubercle bacillus, which some hold to be of low virulence for man, as short and straight. In another place he describes a tubercle bacillus of low virulence obtained from an abdominal abscess as occurring in clumps of ten or more and quite slender, with the chromatin substance more or less transversely segmented.

A tubercle bacillus which has been grown for ten years by Dr. Trudeau showed in old growth a predominance of long, beaded forms with knobs and irregularities. Some were short. In the younger growths short and medium forms occurred which were less beaded. This tubercle bacillus is of very low virulence and injected subcutaneously into a guinea-pig kills only after eigtheen months.

A virulent tubercle bacillus obtained by Dr. Baldwin from an acute case a short time before the observation was made, showed in old cultures chiefly long and beaded forms with a few short and medium-sized bacilli. From new cultures many short forms were obtained, but some were long and showed slightly swollen extremities.

From this it is seen that virulent and attenuated forms of tubercle bacilli possess practically the same morphology and that short bacilli represent usually a younger growth.

In conclusion it may be said:

1. That the examination of one specimen of sputum is of value if tubercle bacilli are found in proving the case one of tuberculosis of the respiratory tract.

2. That if no tubercle bacilli are found one examination is of little value. At least four or five specimens should be examined after the patient is directed how to collect the sputum.

3. That from one specimen little or nothing can be said in regard to prognosis.

4. That if the number of bacilli steadily decrease in a series of examinations at intervals sufficiently long, the patient may be improving, but the constitutional symptoms and local signs give much more accurate information.

5. That if on repeated examinations large quantities of tubercle bacilli are found, the disease has in all probability advanced to cavitation.

6. That the morphology of the tubercle bacilli affords little or no ground for prognosis, but the short bacilli are suggestive of a more active process.

7. That the arrangement of the bacilli in clumps is more apt to be found in the severer cases, but may occur in all.

Clinical Report.

INCISED WOUND OF WRIST,

RESULTING IN PARTIAL DIVISION OF MEDIAN NERVE AND COMPLETE DIVISION OF NEARLY ALL OF FLEXOR TENDONS OF RIGHT HAND.

W. P. VERITY, M.D., and R. L. LARSEN, Ph.D. M.D.
CHICAGO.

The following case is of great interest, from many points of view, especially on account of the circumstances surrounding the etiology, course, treatment and results obtained. The case is one which, in many instances, has often called for repeated and drastic efforts in restoring the pathologic conditions to the normal. The short space of time involved, in which a doubtful result has turned out to be a surprisingly perfect one, is worthy of note.

A boy, Albert P., aged 10 years, resident of this city, came to Dr. Verity's office, June 22, 1901, and showed his injured member. He was accompanied by his mother, who was very anxious to know what could be done to relieve the boy of the inevitable and permanent deformity, which would certainly result if no medical or surgical influence were soon brought to bear.

The parent stated that seven or eight weeks previous to this first visit the boy, while playing in a vacant lot, where there was an abundance of rubbish, stumbled and fell, and in trying to catch himself put out his right arm, his hand striking on some loose pieces of glass lying on the ground, one large piece of glass cutting through the palm of his right hand, at about the bases of the metacarpal bones of the second and third fingers.

The superficial wound in the hand healed, but it left behind it the damage, which forms the center of interest in this paper. No distressing symptom was ever present, as pain, only the discomfort occasioned by the inability to flex the fingers. The wound was considered of a trivial nature and no physician was called.

On examination the following conditions were present: Index and middle fingers could not be flexed, but remained perfectly extended, and ring finger likewise also was affected, only to a less degree. Thumb and little finger retained normal motility. Normal flexion and extension at wrist joint, supination and pronation. No loss of sensation in any of the digits or palm of the hand, a singular fact to note. The laceration in the palm was about ¾ to ⅞ of an inch in length.

Palpation in the region of lower third of forearm and wrist-joint revealed two or three distinctly nodular bodies, which at some points felt sharp, leading to the belief that there were some pieces of glass or other foreign matter present and imbedded in the soft parts. To make certain of these conditions a fluoroscopic and an ordinary *x*-ray picture were taken. The results were negative. These nodules were therefore considered to be the bulbous ends of the severed tendons.

An exploratory operation was advised and consented to. The boy entered St. Joseph's Hospital June 28. Chloroform was the anesthetic used. Median incision, extending from a point at about junction of lower and middle thirds of forearm to a line passing transversely through web of thumb, was made, skin and superficial fascia dissected back, and the following picture presented to view: all the tendons of the flexor sublimis digitorum were completely divided, the cut ends being separated for the distance of nearly three inches. All the tendons of the flexor profundus digitorum, tendons to the index, middle, and ring fingers, were completely severed, with separation in distances ranging from two to four finger-breadths. The central ends of the deep flexor tendons were held down by fibrous bands, each of about an inch and a half in length. These ends, together with central ends of the superficial group, showed nodular swellings, which were irregular in outline, and which, before the operation, puzzled us as to their exact nature. The flexor tendons to the thumb were intact. The only tendon of the long group to the little finger left entire was that of the flexor profundus digitorum.

The conditions were so favorable regarding the patient's disposition that we decided to convert the exploratory operation into a radical one, inasmuch as we had proceeded so far.
